In the geological section an important paper on the continuation of the Saarbrücken Coal-measures into the territory of Lorraine and of France was submitted by Mr. B. Schulz-Briesen (Düsseldorf). In recent years numerous coal discoveries have been made in the Saarbrücken field by the Prussian Government in an area that had been untouched up to the end of the last century, the beds of quicksand above the coal having proved an obstacle. In French Lorraine coal was discovered last year at a depth of 650 metres. A map accompanying the author's paper indicated the coal-bearing area that has been proved, and showed the vast economic importance of the discovery. The genesis of metalliferous deposits and of eruptive rocks formed the subject of a paper by Mr. Paul F. Chalon (Paris). He summed up the matter in the following rules:—primary metalliferous deposits are not met with in stratified rocks that are not traversed by eruptive or igneous rocks; rocks with a fragmental structure contain more metalliferous deposits than compact rocks; in extended areas traversed by eruptive rocks the deposits are never regularly or irregularly distributed, but are concentrated at one or more centres; metamorphic rocks indicating the vicinity of eruptive rocks are favourable for prospecting, particularly in mountainous districts. The geological structure of the mining district of Iglesias, in Sardinia, was described by Mr. G. Merlo. The district is one of considerable economic importance, there being 117 mines in operation, and the value of the mineral output is more than 21 million francs annually. The principal deposits are veins of galena and blende, and contact deposits of galena and calamine. The Palæozoic beds of the district are, in descending order, as follows:—(1) Monteponi sandstone; (2) Gonnesa schist of Silurian age; (3) Cambrian sandstone; (4) metalliferous limestone; (5) Malacalzetta slates. There are thus three horizons of the Cambrian system. The mineral deposits of the banks of the Meuse and of the east of the province of Liége were described by Mr. G. Lespineux. He showed that these calamine masses, like those of the Moresnet district, are not the results of erosion of mineral veins, but were formed in their present condition. The deposit of cinnabar at Monte Amiatia, in Tuscany, was described by Mr. V. Spirek. The deposits occur exclusively in serpentine, and were divided by the author into four classes.

In the metallurgical section the papers read were mostly of a practical character. Mr. Hadfield gave a summary of his researches on the effect of the temperature of liquid air on the properties of steel. Mr. F. Jottrand described a method of cutting metals by a jet of oxygen. The oxyhydrogen blowpipe is directed against the portion to be cut, and heats it to whiteness. The hydrogen is then turned off, and a rapid current of pure oxygen cuts the metal. In practice two blowpipes are used simultaneously, one for heating and one for cutting. The double blowpipe moves at a velocity of 20 centimetres per minute in cutting a steel plate 15 mm. in thickness. The metal is cut almost as cleanly as with a saw. The width of the slit is not more than 2 mm. for plates 15 mm. thick, and is only 3 mm. for plates 100 mm. thick. In order to cut a plate 15 mm. thick there is required per metre cut 540 litres of hydrogen and 540 litres of oxygen, the operation lasting five minutes. Tubes and curved sections can also be cut. Mr. H. Hennebutte described the use of coal poor in agglutinating materials for the manufacture of coke. Mr. E. Bian gave an account of the methods of cleaning blast-furnace gases. Mr. P. Delville read a paper on the influence of titanium on iron and steel. The manufacture of blast-furnace slag cement was dealt with by Prof. H. Wedding and by Mr. C. de Schwarz. Mr. P. Acker described the new modifications of the open-hearth steel process. Mr. R. M. Daelen discussed the methods of obviating "piping" in steel ingots. Electric steel-making processes were dealt with by Mr. G. Gin and by Mr. R.

Pitaval. Mr. L. Guillet, Carnegie scholar of the Iron and Steel Institute, submitted an elaborate monograph on special steels. Of the nickel steels described, the most remarkable are Guillaume's *invar*, with 36 per cent. of nickel, with an elastic limit of 70 to 75 kg. per square mm., a breaking stress of 45 to 55 kg. per square mm., and an elongation of 35 to 25 per cent.; and *platinite*, with 46 per cent. of nickel, with an elastic limit of 60 to 70, a breaking stress of 30 to 40, and an elongation of 45 to 35 per cent. The latter is used instead of platinum in incandescent lamps. The paper summarises in an admirable manner the existing knowledge of nickel, manganese, chromium, tungsten, molybdenum, vanadium, silicon, and aluminium steels. Other papers read in this section dealt with the application of electricity in rolling mills, by Mr. L. Creplet; the double hardening of large steel forgings, by Mr. A. Pierrard; the metallographical examination of iron and steel, by Mr. H. Le Chatelier; and an apparatus for charging mercury furnaces so as to obviate the liberation of deleterious gases, by Mr. V. Spirek.

In the mining section, papers on shaft sinking were read by Messrs. Bodart, Portier, Tomson and Duvivier, and on winding engines by Mr. Henry. The use of superheated steam was dealt with by Mr. Weiss, and the use of steam accumulators by Messrs. Rateau and Chaleil. Modern pumping engines were described by Mr. Schulte, the De Laval high-lift centrifugal pump by Mr. Sosnowski, and the Sulzer high-lift centrifugal pump by Mr. Ziegler. The water-flush system of packing colliery workings was described by Mr. Jüngst and by Mr. Lafitte. Fire-damp detection was dealt with by Messrs. Chesneau, Watteyne, Stassart, and Daniel. Electric haulage was discussed by Messrs. Lapostolet, Halleux, and Henry; and the driving of the great adit-level from Gardanne to the sea was described by Mr. Domage. Altogether the programme was one of great interest, and the discussions on the papers were well sustained. The president of the congress was Mr. Alfred Habets, and the presidents of the sections were:—for metallurgy, Mr. A. Greiner, member of council of the Iron and Steel Institute; for mining, Mr. E. Harzé; for mechanics, Mr. Hubert; and for geology, Mr. Max Lohest. Among the honorary presidents of the sections who presided in turn were:—for metallurgy, Mr. R. A. Hadfield, president, and Mr. H. Bauerman, honorary member of the Iron and Steel Institute; and for mining, Mr. H. C. Peake, chairman of the Institution of Mining Engineers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Prof. G. H. Darwin for the degree of D.Sc. *honoris causa* at the Encænia on June 28:—

Salutamus Georgium Howard Darwin, magni patris magnum filium, non solum inter astronomos insignissimum, sed, ut decebat tali patre ortum, quasi clavis repertorem qua altissima naturæ arcana reseraret. Ille quidem, Carolum dico, de vita animantium doctor insignissimus, ostenderat quo modo sensim immutata figura simplicioribus et rudioribus perfectiora animalia succederent: hic noster docuit quo modo ipsa mundi compages lentas mutationes subiret. Duces quidem in hac re secutus est Newtonum, Laplacium, Kelvinum, sed suis viribus fretus est magis. Quid enim? Omnia quæ de reciproco maris motu litteris tradita sunt ipse denuo pertractavit, siderum cælo decurrentium meatus summa diligentia et scientia amplissima investigavit: idem tenuissimo quoque et subtilissimo mathematicæ genere instructus, ingenio audaci et vegeto pollens, luculentissime ostendit quo momine et nutu variæ maris agitationes tam multiplices gignantur: quod cum faceret id assecutus est ut terræ, lunæ, solis, planetarum primordia et vices satis clare adumbraret. In hoc viro agnoscimus hominem, dictu mirum, mundorum nascentium annales conscribentem.

CAMBRIDGE.—The Raymond Horton-Smith prize for 1905 has been awarded to Dr. W. L. H. Duckworth, of Jesus College, for a thesis for the degree of M.D. entitled "On the Nature of Certain Anomalous Cases of Cerebral Development."

SUBJECT to the Enfield Council agreeing to contribute one-third of the total cost of the buildings and necessary alterations, it has been decided by the Middlesex County Council to acquire the Ediswan Institute, Ponders End, the object being to convert it into a technical institute for the eastern portion of Enfield, that suitable technical instruction may be given to those engaged in the Small Arms Factory, Enfield Lock, the works of the Edison and Swan Co., &c.

A NEW movement for the encouragement of tropical research has been inaugurated in connection with the University of Liverpool. The school of research, of which Lord Mountmorres is to be the first director, will seek in every way to inquire into the natural resources of the tropical possessions of the Empire. Sir Alfred Jones, of the Elder-Dempster line of steamers, has promised to contribute 1000*l.* a year for four years towards the expenses of the movement.

ACCORDING to *Science*, the following appointments have recently been made in America:—Dr. A. W. Harris, president of North-western University; Dr. C. H. Smyth, professor of geology at Princeton University; Dr. N. Senn, professor of surgery, and Dr. F. Billings, professor of medicine, at the University of Chicago; Dr. H. K. Wolfe, professor of philosophy and education at the University of Montana; Mr. I. E. Wallin, professor of natural history in Upsala College, New Orange, N.J.

THE department of general pathology and bacteriology of King's College, London, announces a course in clinical and practical bacteriology suited to the requirements of medical practitioners and senior students. The course, which will begin on July 26 and end on August 5, will consist of lectures, demonstrations, and practical work. In connection with the same department there will be from July 27 to August 4 a vacation course in clinical pathology consisting of demonstrations and practical work. Further particulars may be obtained from Prof. Hewlett or the secretary of the college.

DURING the coming session courses of general and experimental psychology will be held at King's College, London. During the first and second terms Prof. Caldecott will deliver a series of lectures on general psychology. Prof. W. D. Halliburton, F.R.S., will lecture during the first term on the general structure and histology of the nervous system and of the organs of sense. During the second and third terms lectures on experimental psychology, accompanied by demonstrations and laboratory work, will be given by Dr. C. S. Myers in the new psychological laboratory. A departmental library has been opened at the college containing the principal English and foreign books and journals devoted to psychology.

THE Department of Agriculture and Technical Instruction for Ireland has issued its regulations and syllabuses to guide the teaching of science in Irish day secondary schools for the session 1905–6. The complete conditions regarding regulations for grants, qualifications of teachers, syllabuses of subjects, and a list of official forms are now issued in a single volume. The regulations are materially the same as those which were in force during last session. Some few syllabuses have been modified in the light of the experience gained in the last two years. It is announced that the summer courses for teachers will be continued as heretofore, but it is hoped they will, after 1908, develop into "post-graduate courses on special subjects for those already qualified."

THE British University Students' Congress met on June 28 at University College. All the universities of the United Kingdom were represented except Oxford and Cambridge, these having no organisation which can send delegates to represent their undergraduates generally. The report of the subcommittee appointed last year to consider the question of residential halls at home and abroad was presented. Fourteen British universities and colleges,

eleven American universities, and four Australian universities have been communicated with. It was resolved to elect a committee to formulate recommendations as to what should be done to help to develop the residential system. It was decided also to extend the scope of the constitution of the congress so as to include delegates from the universities of Ireland as well as of England and Wales, and to invite universities of Scotland also to send representatives annually.

It is announced that Mr. J. D. Rockefeller has given 2,000,000*l.* to the General Educational Board, a body incorporated by a recent Act of Congress for the purpose of promoting education in the United States, and the income is to be used for the extension of higher education in the United States. Mr. Rockefeller has also presented 200,000*l.* to Yale University. It is stated the gift to the Educational Board is to be held in perpetuity, and the income, after payment of administrative expenses, is to be used for the benefit of such institutions as the Board may select for periods, in amounts, for purposes, or on conditions to be determined by the Board, which may also employ the income in such other ways as it may deem best adapted to promote a comprehensive system of education in the United States. The income is to be used without distinction of locality, and its use is to be confined to higher education. It is designed especially for colleges as distinguished from the great universities, although there is no prohibition of grants to universities. The benefits of the donation are to be open to all, although the fund cannot be employed for giving specifically theological instruction. The fund may be used for endowment, for building, for paying off debts, or meeting current expenses.

The report for the year 1904 of the council to the members of the City and Guilds of London Institute has been received. We notice that the number of university students attending the Central Technical College continues to increase, and that more than 110 such students are in attendance during the current session. At the last degree examination in engineering for internal students of the university, open to all engineering schools in London, eleven degrees in all were conferred, and of these eight were obtained by this college. The total number of students in the college during 1904 was 409, as compared with 304 in the preceding year. This increase in number of the students has made it necessary to provide an increase in the teaching staff, and the appointment of five new assistants has been sanctioned at a cost in salaries of 800*l.* a year. The council, in their last report, announced the steps which had been taken towards the extension of the building of the Technical College at Finsbury. Since then the plans of the new building have been approved, a tender accepted, the foundations excavated, and the building begun. In settling the details of the plans and on the question of the equipment of the new building, the committee had the benefit of the advice of Sir William White, K.C.B., F.R.S. The work of the department of technology of the institute continues to increase with the growing demand for instruction in the application of science and art to specific industries and trades. There are two directions in which, in the opinion of the council, improvements might be effected in the technical education of artisans. First, in the preparation of students before entering upon their courses of evening technical instruction, and secondly, in the standard of qualifications of the teachers nominated by local authorities to give such instruction. It is satisfactory to find that in the different branches of technology the number of students registered as attending classes in the United Kingdom was 41,089, as compared with 38,638 in the previous year. The report as a whole is an excellent record of a substantial year's work.

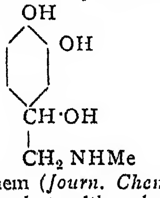
SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, June 7.—Mr. F. Merrifield, president, in the chair.—An earwig, *Apterygida arachidis*, Yers., found by Mr. Annandale, of Calcutta, in a box of specimens received from the Andaman Islands: M. **Burr.** When placed in a small box the earwig was alone, but next morning there were five larvæ present; two disappeared, apparently being consumed by the parent, and the remaining three were those exhibited. Mr. Burr also showed a locustid of the family Pseudophyllidæ, taken in Queensland by Mr. H. W. Simmonds among twigs and plants which it greatly resembled, together with a photograph of the insect in its natural position.—(1) Three examples of *Gnorimus nobilis*, L., taken at Woolwich on May 20 last under the bark of an old dead cherry tree, a beetle supposed to be becoming extinct in Britain; (2) a malformed specimen of *Lochmaea suturalis* which had the left posterior tibia bifid for about one-third of its length, and two tarsi, one of which had the joints considerably enlarged: E. C. **Bedwell.**—A living specimen of *Omophlus betulae*, Herbst, a beetle not known to occur in Britain, found near Covent Garden, and probably imported: O. E. **Janson.**—One ♂ and three ♀♀ of *Agrion armatum* taken this year by Mr. F. Balfour Browne, and sent to the exhibitor alive: W. J. **Lucas.**—Four specimens of the rare *Acrognathus mandibularis*, Gyll, captured on the wing towards sunset near Woking at the end of May: G. C. **Champion.**—Two aberrations of *Biston hirtaria*, Cl., both females, taken at rest on tree-trunks at Mortehoe, North Devon, April 23: Selwyn **Image.** The first aberration was tolerably normal in general coloration, but the anterior half of the fore-wings was much suffused with fuscous, and at the costa was broadly emphasised with rich black. The second aberration was semi-transparent black all over both fore- and hind-wings, the veins strongly delineated with black, powdered with ochreous.—Empty pupa-cases of *Zonosoma pendularia* demonstrating the wide variation of methods in the placing of the silken girth round the pupa: W. J. **Kaye.**—Leaves of strawberry, *Berberis japonica*, and cherry-laurel which had been attacked by a minute fungus—in the case of the Berberis identified by Prof. S. H. Vines as *Phyllosticta japonica*, Thnem.: Prof. E. B. **Poulton.** The attack was local, leaving a roundish or oval window outlined with brown, sometimes in the form of a narrow line, sometimes spreading peripherally into the leaf for a greater or less distance. In the strawberry leaves the edges of the windows were somewhat ragged, but those of the other two leaves had smooth contours, and resembled strikingly the oval transparent areas upon the fore-wings of *Kallima inachis*, *K. paralekta*, &c. Prof. Poulton had believed that these "windows" of Kallima represented holes gnawed by larvæ, and that the altered marginal zone reproduced the effect of the attacks of fungi entering along the freshly exposed tissues of the edge. But he now desired to withdraw his earlier hypothesis in favour of the more probable and convincing suggestion made by Mr. Grove.—Photograph of the fungus-like marks on the wings of the Oriental Kallimas: Prof. **Poulton.**—The variability of the genitalia in Lepidoptera: Dr. Karl **Jordan.**—Scents in the male of Gonepteryx: Dr. G. B. **Longstaff.** It was mentioned that whereas in *G. cleopatra* ♂ the odour was strong, the author had been unable to detect any appreciable fragrance in *G. rhamni* ♂. Such a difference, he said, seemed to imply a physiological difference of the two forms pointing to specific distinction. Dr. F. A. Dixey, in connection with Dr. Longstaff's observations, exhibited and explained the several forms of Gonepteryx occurring in the Palæarctic region.—The geographical affinities of Japanese butterflies: H. J. **Elwes.** Summing up his remarks, the author said that during the winter and spring months the plants and insects of Japan were, like the climate, Palæarctic in character, yet during the summer and autumn they were tropical.—New African Lasiocampidæ in the British Museum: Prof. C. **Aurivillius.**—Memoir on the Rhynchota taken by Dr. Wyllie chiefly in Beira and Lifû: G. W. **Kirkaldy.**

Chemical Society, June 14.—Prof. R. Meldola, F.R.S. president, in the chair.—Influence of various sodium salts on the solubility of sparingly soluble acids: J. C. **Philip.**—The dielectric constants of phenols and their ethers dissolved in benzene and *m*-xylene: J. C. **Philip** and Miss D. **Haynes.**—Synthesis by means of the silent electric discharge: J. N. **Collie.** The facts of special interest are that ethylene under the influence of the silent electric discharge at the ordinary temperature will unite with carbon

monoxide, and will also polymerise, yielding a series of complicated hydrocarbons; the chief substances formed boil at about 150°–160°, and apparently approximate in composition to $C_{10}H_{20}$.—The ultra-violet absorption spectra of aromatic compounds, part i., benzene and certain mono-substituted derivatives: E. C. C. **Baly** and J. N. **Collie.** The ultra-violet absorption spectra of benzene and of some of its mono-substituted derivatives were described. It has been found that benzene presents seven separate absorption bands, and it was shown how the formation of these may be accounted for by attributing each one to a separate and distinct process of dynamic isomerism connected with the linkage changes within the benzene molecule. A similar explanation of the absorption spectra of benzene mono-substituted derivatives was given.—The ultra-violet absorption spectra of aromatic compounds, part ii., the phenols: E. C. C. **Baly** and E. K. **Ewbank.** The absorption band produced by the dynamic isomerism existing in solutions of acetylacetone and similar tautomeric substances of the aliphatic series occupies very nearly the same position as the band given by phenol. The existence of a similar type of dynamic isomerism in the case of phenol is suggested as explaining the difference between the spectra of phenol and its ethers.—Association in mixed solvents: G. **Barger.**—Synthesis of substances allied to epinephrine: G. **Barger** and H. A. D. **Jowett.** The authors have attempted to synthesise a compound having the formula



proposed by one of them (*Journ. Chem. Soc.*, 1904, lxxxv., 192) for epinephrine, but although the methylene and dimethyl ethers were prepared, the base itself could not be isolated.—The determination of melting points at low temperatures: L. F. **Guttmann.** A method has been worked out for readily determining melting points at low temperatures (−142° to −55° is the range so far used) by means of a constantan-copper couple connected to a delicate galvanometer.—The action of water on diazo-salts, a preliminary note: J. C. **Cain** and G. M. **Norman.** One of the authors has shown that little or no hydroxy-compound is obtained by boiling certain ortho-substituted diazo-salts of the diphenyl series with dilute acids. A number of similarly substituted compounds which are said not to yield phenols on boiling with water or acids have now been examined.—A precise method of estimating the organic nitrogen in potable waters: J. C. **Brown.** The process consists in distillation to dryness of a mixture of a portion, without previous evaporation, with potassium hydroxide and potassium permanganate. The ammonia evolved is estimated by Nessler's solution.—Synthesis of 1 : 1-dimethyl-Δ^3-tetrahydrobenzene: A. W. **Crossley** and Miss N. **Renouf.**—Bromine in solutions of potassium bromide: F. P. **Worley.**—The solubility of bromine in aqueous solutions of potassium bromide has been determined over a wide range of concentrations at 18°·5 and 26°·5. There are indications that with the higher concentration of bromine, compounds more highly brominated than KBr_3 are produced.—Tetramethylammonium hydroxide: J. **Walker** and J. **Johnston.** A solution of tetramethylammonium hydroxide is readily prepared by mixing alcoholic solutions of tetramethylammonium chloride and potassium hydroxide.—Tetrethylsuccinic acid: J. **Walker** and Mrs. A. P. **Walker.**—The ultra-violet absorption spectra of aromatic compounds, part iii., disubstituted derivatives of benzene: E. C. C. **Baly** and E. K. **Ewbank.**—Studies in chlorination, ii., the action of chlorine on boiling toluene, preliminary notice: J. B. **Cohen,** H. M. **Dawson,** and P. F. **Crosland.** The results show that, under the conditions of the experiments, electrolytic chlorine enters the nucleus only, and also that the rate of chlorination appears to be more rapid than with ordinary chlorine evolved from pyrolusite and hydrochloric acid.—Purpurogallin: A. G. **Perkin.** A description of various derivatives is given.—The electrolytic oxidation of hydroxybenzoic acids: A. G. **Perkin** and F. M. **Perkin.**

PARIS.

Academy of Sciences, June 26.—M. Troost in the chair.—On a determination of the constant of aberration by means of observations of three stars very close to the pole: H. **Renan** and W. **Ebert.** Arising from researches on the determination of latitude and of the absolute coordinates of the circumpolar stars, a long series of accurate observations has become available for the calculation of the constant of aberration. An advantage of this method is that no correction is necessary for the variation of latitude. The final value obtained is 20″·434, with a probable error of 0·030s.—On isothermal surfaces: L. **Raffy.**—The motion of the earth and the velocity of light: M. **Brillouin.** An analysis of the method proposed by M. Wien and M. Schweitzer for solving the problem as to whether the ether is carried on by the earth, in which the author shows that the desired result will not be attained.—An apparatus for controlling actions produced at a distance by means of electric waves: Édouard **Branly.** An account of alterations in an apparatus already described, the chief improvement being the substitution of an electric motor for the clockwork movement.—On the specific inductive power of metals: André **Broca.** In a preceding note the author, with M. Turchini, has shown that the experimental results are not in accord with the theory for the resistance of fine metallic wires for continuous currents and alternating high frequency currents, the calculations being carried out according to Lord Kelvin's hypothesis. In the present note it is shown that the introduction of the specific inductive power, neglected in the first calculations, will account for the observed differences.—On the phenomena of the singing arc: A. **Blondel.**—An apparatus and method for measuring coefficients of magnetisation: Georges **Meslin.** A modification of the arrangement proposed by MM. Curie and Chenéveau.—The hydrolysis of very concentrated solutions of ferric sulphate: A. **Recoura.** A concentrated solution of ferric sulphate in a well closed vessel becomes slowly converted into a solid basic sulphate and a soluble acid sulphate. From the time required for this change the author regards this action as not due to a simple hydrolysis, but as due to a molecular transformation.—Combinations of aluminium chloride with carbonyl chloride: E. **Baud.** Three compounds of these substances are shown to exist, containing aluminium chloride and carbonyl chloride in the following molecular ratios, 1 : 5, 1 : 3, and 2 : 1. The last is found in commercial aluminium chloride.—The constitution and properties of steels containing tin, titanium, and cobalt: Léon **Guillet.** These metals enter into solution in the iron, the carbon being in the form of carbide. The mechanical properties of these steels are such as to prevent their commercial application.—On the reduction of aldoximes: A. **Mailhe.** Aldoximes can be readily reduced to amines by the Sabatier and Senderens reaction, but the primary amine is not the only product. Acetaldoxime gave a mixture of the primary, secondary, and tertiary amines, and œnanthaldoxime behaved similarly; owing to the decomposing action of the reduced nickel on benzaldoxime the reduction of this compound was irregular.—On the bromination of paraldehyde: P. **Freundler.** At a low temperature bromoacetaldehyde can be obtained; under different conditions tetrabromobutyric aldehyde is produced.—On some new β-keto-aldehydes: F. **Couturier** and G. **Vignon.**—The iodomercurates and chloroiodomercurate of monomethylamine: Maurice **François.**—On some derivatives of butyroine and capronoine: L. **Bouveault** and René **Locquin.**—On a bivalent phytosterine alcohol: T. **Klobb.** This alcohol, described in a previous paper under the name of arnisterine, a neutral crystalline principle extracted from *Arnica montana,* has now been shown by its reactions with acetic anhydride, benzoyl chloride, and phenyl isocyanate to be an alcohol containing two hydroxyl groups, and it is proposed to revise the name to arnidiol.—A method for determining the purity of cocoa butter: E. **Milliau.**—The toxicology of mercury-phenyl: E. **Louise** and F. **Moutier.** This substance proves to be only very slightly toxic in comparison with the corresponding compounds of the fatty series.—On the combustion of sulphur in the calorimetric bomb: H. **Giran.** In a preceding paper the author has attributed the variation of the heat

of combustion of sulphur with pressure to the formation of persulphuric acid, but calorimetric determinations carried out with this substance show that this view is incorrect. The effects observed are due to the presence of traces of hydrogen and nitrogen in the compressed oxygen employed.—Oxyhæmoglobin from the guinea-pig, and its reaction with fluorides: M. **Piettre** and A. **Vila**.—On the simultaneous variations of the organic acids in some plants G. **André**.—On the production of a soft cider: G. **Warcollier**. The must prepared for fermentation is freed as far as possible from oxygen, and the fermenting liquid is protected from the air during the process.—The genus Alabes of Cuvier: Léon **Vaillant**.—The physiological signification of the urate cells in solitary honey-bearing insects: L. **Semichon**.—The hæmolytic action and general toxicity of eel serum for the marmot: L. **Camus** and E. **Gley**.—On the presence of poison in the eggs of the viper: C. **Phisalix**. At the moment of ovogenesis in the viper the active principles of the venom accumulate in the ovules, and probably play a part in the development.—On the problem of statical work: Ernest **Solvay**.—The treatment of cutaneous cancer by radium: Jules **Rehns** and Paul **Salmon**. A description of two cases in which radium was used with successful results.—On the existence of a remarkable Pliocene layer at Tetouan, Morocco: Louis Gentil and A. **Boistel**.—On the origin of eoliths: Marcellin **Boule**.—The drawings of the lion and cave bear and of the *Rhinoceros tichorhinus* on the walls of caves by man in the reindeer epoch: MM. **Capitan**, **Breuil**, and **Peyrony**.

GÖTTINGEN

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts i. and ii. for 1905, contains the following memoirs communicated to the society:—

February 11.—O. **Wallach**: Researches from the university chemical laboratory, xiv.:—(1) on the constituents of the sage-oils; (2) on the proportion of phellandrene in the ethereal oil of *Schinus molle*, L.; (3) on the occurrence of an alcohol with the properties of pinocarveol in the ethereal oil of *Eucalyptus globulus*; (4) on the semi-carbazone of *d*- and *l*-fenchone, and the occurrence of *l*-borneol ester in Thuja-oil; (5) on the preparation and behaviour of methyl(1)-phenyl(2)-hexene; (6) on the bromine-substitution-products of cyclohexanone and cyclopentanone.

January 28.—A. **von Koenen**: On the underground effects of earth-pressure in salt-mines.

February 2.—Dr. H. **Schering**: Seismic records at Göttingen in the year 1904.

February 11.—W. **Biltz**: Further contributions to the theory of tinctorial processes. (1) Measurements relating to the formation of inorganic analogues of substantive dyes; (2) on the "affinity of condition" of certain sulphuretted dye-stuffs.

February 25.—W. **Nernst** and H. **von Wartenberg**: On the dissociation of water-vapour. W. **Nernst** and H. **von Wartenberg**: On the dissociation of carbonic anhydride. E. **Wiechert**: Remarks on the motion of electrons with velocities exceeding that of light. C. **Carathéodory**: On the general problem of the calculus of variations. L. **Maurer**: On the differential equations of mechanics. M. **Laue**: On the propagation of radiation in dispersive and absorptive media. T. **Tamaru**: Determination of the piezoelectric constants of crystallised tartaric acid. (1) General sketch of theory and method of observation; (2) pressure arrangements and the piezoelectric excitation; (3) electrometric methods; (4) results. D. **Hilbert**: Contributions to the calculus of variations.

NEW SOUTH WALES.

Royal Society, May 3.—Prof. Liversidge, F.R.S., vice-president, in the chair.—On the occurrence of calcium oxalate in the barks of the Eucalypts: Henry G. **Smith**. The author announces the presence, in large quantities, of calcium oxalate in the barks of several species of Eucalyptus. It is similar in form and appearance in all species, being well defined monoclinic crystals in stout microscopic prisms, averaging 0·0174 mm. in length and 0·0077 mm. in breadth, and containing one molecule of water. A peculiarity of these is the tendency to form twins geniculate in appearance, twinned forms being pronounced in some species. From botanical and chemical evidence it is assumed that *Eucalyptus salmonophloia* of West Australia and *E. oleosa* of New South Wales belong to the same species, and that the latter tree, which most often occurs as a "mallee," is only the degenerate stage of the former. The theory is advanced that some of the "mallees," or shrubby Eucalypts, have been formed through the poisoning effect of the excess of oxalic acid acting for a long time upon species which originally grew as large trees. The tannins in those Eucalyptus barks containing a large amount of calcium oxalate are of very good quality, light in colour, astringent, easily soluble, and should make leather of good quality. On evaporating the extract to dryness on the water bath but little darkening takes place, and the product is still readily soluble. This class of Eucalyptus barks should, therefore, make excellent tanning extracts. From the bark residue the calcium oxalate should be profitably extracted, and the oxalic acid obtained cheaply from this, practically as a by-product. The air-dried bark of *Eucalyptus salubris*, the "gimlet" of West Australia, gives 30·5 per cent. of total extract and 18·6 per cent. of tannin absorbed by hide powder, and contains 16 per cent. of calcium oxalate. The bark of *Eucalyptus gracilis* contains 16·66 per cent. of calcium oxalate, that of *E. Behriana* 16·5 per cent., of *E. oleosa* 10·64 per cent., of *E. dumosa* 9·8 per cent., and of *E. salmonophloia* 8·34 per cent. The barks of all the Eucalypts tested contain calcium oxalate, although in some species in very small amount.—Notes of astronomical interest, dealing with the past eighteen months, showing the progress and deductions made during that period: H. A. **Lenehan**.

DUBLIN.

Royal Irish Academy, May 22.—Prof. R. Atkinson, president, in the chair.—On the vegetation of the southern part of county Dublin: G. H. **Pethybridge** and R. Lloyd **Praeger**. The paper dealt with the plant associations of this area, which extends from sea-level to nearly 2500 feet, and embraces more than 200 square miles. A coloured vegetation map and photographs were shown in illustration of the subject.

THURSDAY, JULY 13, 1905.

THE POPULARISATION OF SCIENCE.

The New Knowledge. By Robert Kennedy Duncan, Professor of Chemistry in Washington and Jefferson College. Pp. xviii+263. (London: Hodder and Stoughton, 1905.)

THE author of this attempt to make the progress of recent discovery in chemistry and physics understanded of the people remarks in his preface:—

"The great expositors are dead, Huxley and Tyndall and all the others; and the great expositor of the future, the interpreter of knowledge to the people, has yet to be born."

And (but it must be added quite modestly) he attempts to wear the cloak of the prophet. He is right, on the whole, when he says that "the progressive teacher, particularly in the high school or smaller college, finds it often exceedingly difficult to gain access to the original sources of knowledge," and, it may also be remarked, to understand them when he does. Hence any serious attempt made by one sufficiently versed in science to avoid error, and with sufficient appreciation of the difficulties of one who has not made science his speciality to know how to present facts and their interpretation, is deserving of a cordial welcome. Indeed, most scientific men are in the position of outsiders towards sciences not their own; and an allusion to the recent effort made by the Chemical Society to present the year's progress to their Fellows is here not inappropriate, for to such an extent is specialisation now carried that it is practically impossible for the physical chemist to follow the researches of the organic chemist, and *vice versâ*. Their "Annual Reports on the Progress of Chemistry for 1904" will be much appreciated by all chemists. It is true that the organic chemist, for example, may consider the amount of space devoted to his branch insufficient, and the treatment of the subject-matter somewhat scrappy; yet to one who has no time to follow in detail the work of the specialists published in numerous journals during the year, a summary like this is of the greatest value. It is very desirable, in subdivisions of a science, as well as in separate sciences, that the bearing of one branch of knowledge on another should be realised, and so far understood; and the Chemical Society is to be congratulated on its new effort. It is to be hoped that a similar plan will be adopted by physiologists, geologists, and, indeed, by all those who labour for the "promotion of natural knowledge."

But to return to Prof. Duncan's book. Beginning with the "three entities," matter, ether, and energy, an attempt is made in seven pages to give the reader some idea that these are the conceptions in terms of which the modern man of science interprets nature. The doctrines of the conservation of mass and of energy, and the necessity for the assumption of the existence of ether are indicated. I doubt whether an entire outsider would gain much by reading this chapter; still, if it stimulates him to think, and to try to acquire clearer ideas on the subject, much will have been accomplished. We have then certain elementary conceptions of chemistry expounded, molecules, atoms, compounds, and elements, and so closes part i., which consists of eleven pages.

To give the reader an idea of the author's style, a quotation from the first paragraphs of part ii. may be made.

"We believe—we must believe, in this day—that everything in God's universe of worlds and stars is made of atoms, in quantities x, y or z respectively. Men and women, mice and elephants, the red belts of Jupiter and the rings of Saturn are one and all but ever shifting, ever varying, swarms of atoms. Every mechanical work of air, earth, fire and water, every criminal act, every human deed of love or valor: what is it all, pray, but the relation of one swarm of atoms to another?

"Here, for example, is a swarm of atoms, vibrating, scintillant, martial,—they call it a soldier,—and, anon, some thousands of miles away upon the South African veldt, that swarm dissolves,—dissolves, forsooth, because of another little swarm,—they call it lead.

"What a phantasmagoric dance it is, this dance of atoms! And what a task for the Master of the Ceremonies. For mark you the mutabilities of things. These same atoms, maybe, or others like them, come together again, vibrating, clustering, interlocking, combining, and there results a woman, a flower, a blackbird or a locust, as the case may be. But to-morrow again the dance is ended and the atoms are far away; some of them are in the fever germs that broke up the dance, others are 'the green hair of the grave,' and others are blown about the antipodes on the winds of ocean. The mutabilities of things, and likewise the tears of things: for one thing after another,

'Like snow upon the Desert's dusty Face
Lighting a little hour or two—is gone,'

and the eternal, ever-changing dance goes on."

Now this purports to be very fine writing, but does it gild the pill of science? I am inclined to think not. Still, tastes may differ.

It would be unfair to judge of the book, however, by this quotation. The subsequent sections deal with the periodic classification, gaseous ions, corpuscles, and here a very lucid account is given of the method of estimating the velocity of a corpuscle, and of the relation of the charge to the mass; really in these sections the author has established his character as a clear expositor. Positive ions are then considered, and then natural radio-activity, in which there is a capital sketch of the discovery of radium and of its properties. A subsequent chapter treats of thorium, uranium, radium, and actinium, with the reproduction of Prof. Rutherford's latest results, and the section concludes with the radio-activity of substances in general. The next "part" deals with the resolution of the atom and with atomic disintegration, and an intelligible account is given of Prof. J. J. Thomson's most recent work. The heat-emitting property of radium is next dealt with, and then there is a summary of the "electrical nature of matter." The book concludes with part v., entitled "Inorganic Evolution and Inorganic Devolution," discussing intelligently and intelligibly Sir Norman Lockyer's theories

relating to stellar temperatures and stellar change, and the problems of the sun's heat, the mechanical pressure of light, and the re-construction of a universe are the concluding chapters. The last chapter of all, the validity of the new knowledge, deals with the question, Is all this true? And here there is a touch of philosophy. For "A system is 'true' if it is entirely consistent and coherent, if it is completely self-explanatory."

"There is no criterion of absolute truth, there is no way of attaining to absolute truth, and we may as well acknowledge it. Should we therefore abandon the world-riddle? Assuredly not. If we may never *know* a system to be true, we may *believe* it to be true. We may not have a knowledge of truth, but we may have a recognition of it." "Meanwhile this system of the new knowledge . . . is simply the outermost circle covering the greatest area of knowledge, and while its diameter is by no means infinite, it is the truest expression of the truth attainable at this time, and as such is vastly useful. Its utility in the evolution of knowledge is its sole apology for existence."

This work is the first attempt which I have seen to bring into suitable compass, in an intelligible manner, the various problems which are occupying the attention of many physicists and chemists. There are few errors, and these are unimportant. Whether the author might not have omitted much fine writing is a question of taste. But even if it be regarded as ill-placed, it does not destroy the intrinsic value of his work. W. R.

THEORETICAL GEODESY.

Trattato di Geodesia Teoretica. By Paolo Pizzetti. Pp. ix+467. (Bologna: Zanichelli, 1905.)

SIGNOR PIZZETTI has treated the subject of geodesy in a thoroughly exhaustive manner. The theoretical portion of the book, dealing with the formulæ used in geodesy, is very ably demonstrated, and the mathematical proofs of the various problems are sufficiently clear to be easily followed by those practically uninitiated in the subject. The same, however, cannot be said of the descriptive narrative of geodetical operations in general. The book, in fact, impresses one far more from the theoretical than from the practical point of view. The absence of practical demonstrations of the use of the various formulæ must be a great loss in a work of this nature, and for this reason it compares unfavourably with such standard treatises as Puissant's "Traité de Géodesie" and Clarke's "Geodesy," where ample practical illustrations of the application of geodetical formulæ are given to help the student in this complicated subject. Even a few examples taken from any modern geodetic triangulation would have been of the greatest assistance. Theory alone is almost bound to have a deterrent effect.

The book contains a short and concise history of the several hypotheses as to the form and constitution of the earth prior to any actual geodetical operations, but the account of the several measurements of "arcs of meridian" is very meagre, and confines itself practically to mentioning those measured in Peru and Lapland in the eighteenth century.

Doubtless these "arcs" played a most important part in geodesy, but subsequent measurements have been of equal importance, and have been carried out with the advantage of superior knowledge and more perfect instruments.

Like most Continental geodesists, the author adheres to the data for the figure of the earth deduced by Bessel in 1840, and it is only in an appendix that any reference is made to Clarke's determination. This, I think, is scarcely fair to English geodesy, considering that Clarke had the advantage of a far larger number of arcs whence to deduce his values, as given in his excellent treatise in 1880. A reference to these values should find a place in every standard work on geodesy, and it is noteworthy that the American Geodetic Survey, which previously employed Bessel's values, has, within recent years, discarded them in favour of Clarke. This was in great part due to the close agreement between Clarke's values and those deduced by the Americans themselves in their various arc measurements.

Several chapters are devoted to the mathematical proof of the various functions of a spheroid of revolution. On the whole, they are easily followed, and differ but slightly from those used by Puissant in his great work. The formulæ in chapter iv. for the determination of the geographical coordinates are similar to those used in the Indian auxiliary tables. Here, particularly, the want of definite examples is greatly felt, and I cannot but think that Signor Pizzetti would greatly enhance the value of his work by adding a few taken at hazard from any survey. The actual illustration given in this chapter is one but rarely used in geodesy.

Three chapters are given up to the description of base measurements and the practical observation of geodetic angles. It may at once be said that the account is far from thorough, and the practical student desirous of studying the methods to be employed in the field would glean but a scanty knowledge. Mention is made of some of the more important instruments used in base measurement, such as Borda's rods, Ibenaz's apparatus, and the American contact duplex bars, but no word is given of Colby's compensation bars, and only the slightest reference is made to measurements by means of steel or invar tapes or wires. There is little doubt that in future all geodetic bases will be measured by the latter means. Only quite recently in South Africa bases have been measured with an extraordinary degree of precision with invar wires.

As regards the measurements of the angles, there is but little information as to the practical work to be done, but a very exhaustive treatise is given of the causes of the various instrumental errors. It is mainly in agreement with those chapters in Chauvenet's "Astronomy" dealing with this subject.

Reference is made to the various instruments used for astronomical work, such as transit—altazimuth—and zenith telescopes. The various errors to which such instruments are liable is very carefully gone into.

A short history is given in chapter viii. of the general development of triangulation from the time of Snellins to the present day, but it consists mainly in mentioning some of the more striking incidents connected with the subject, such, for instance, as the use of electric light in the work connecting Spain and Algiers.

The question of lateral refraction is gone very fully into, and a table is given showing the mean triangular errors proportional to triangles of different sizes. The deduction is then made that the effect of lateral refraction increases with the mean length of a side of a triangle up to about 90 kilometres, after which it begins to decrease again. This is a particularly interesting problem, and the table, which is taken from a recent triangulation in Germany, certainly confirms the deduction. It is of course assumed that the closing errors of triangles are due in most part to lateral refraction. The usual methods of calculating and computing triangulation are very thoroughly dealt with.

Precise levelling forms the greater part of chapter ix., but an exceedingly full and clear demonstration is given at the beginning of the various formulæ relative to atmospheric refraction and to trigonometrical differences in heights of stations. This is treated in a really very clear manner.

Three chapters are devoted to the theory of probability and its application to geodesy. The theoretical portion has been well demonstrated, and differs but little from the numerous text-books on this subject; but where the attempt is made to apply the method of least squares to a network of triangulation, the want of taking a practical example is at once felt. Clarke, in his "Geodesy," gives numerous examples of how to apply theory to practice, but Signor Pizzetti leaves the student utterly in the dark on this important point.

Perhaps the two most interesting chapters are left to the end. They deal with the subject of projections, which is gone into with every care. There is scarcely any well known projection which is not very fully explained.

Altogether this book is a distinct addition to any geodetic library. W. J. JOHNSTON.

OUR BOOK SHELF.

The Food Inspector's Handbook. By Francis Vacher. Fourth edition. Pp. xvi+231; illustrated. (London: The Sanitary Publishing Co., 1905.) Price 3*s*. 6*d*. net.

THIS is a pocket volume intended for the use of sanitary and other officers concerned in the inspection of food. It describes, in simple, untechnical language, the naked-eye characters of the various foodstuffs met with in ordinary commerce, and points out the physical signs by which unwholesome food may be detected.

The first sixty pages deal chiefly with the statutory powers by virtue of which the food-supply of the community is supervised. They include a summary, with explanatory comments, of the various enactments —Public Health Act, Sale of Food and Drugs Acts, and so on—bearing upon the control of food from the inspector's point of view. Next follow chapters treating of meat, poultry, and fish. This is the most important part of the book, and the notes upon the *ante-* and *post-mortem* signs of those diseases which render flesh-food unfit for consumption, or which seriously depreciate its quality, will be especially valuable to sanitary officers who have had no veterinary experience. A subsequent chapter is allotted to fruit and vegetables, and one to milk; the rest of the book gives short descriptions of cereals, dairy products, tea, sugar, spices, and so forth. This section, though of interest to the food inspector, is of less concern to him than the foregoing, the quality of the articles mentioned being generally a matter for decision by analysis, not for condemnation at sight.

The author gives sensible advice, and his little volume should be found very useful to those for whom it is written. The only inaccuracy we have noted is suggested in the statement that "Dutch cheese is below the standard per cent. as regards fat"; this might imply that there is a legal standard, which is not the fact. C. S.

Manuale dell'Ingegnere Elettricista. By Attilio Marro. Pp. xv+689. (Milan: Ulrico Hoepli, 1905.) Price 7.50 lire.

THIS book forms one of the useful series of "Manuali Hoepli," which already comprises over 800 distinct treatises. Its aim is to give to engineers and electrical constructors most of the information and data that they are likely to require in practice. On this account it is not so much a text-book as a classified collection of rules and data; but on account of its containing a large amount of explanatory matter it lies intermediate between a treatise on electrical engineering and a pocket book of electrical rules and tables. The type being small but clear, a very large amount of useful information is collected in a small compass. The numerical data have been obtained principally from recent papers published in the journals of electrical engineering, and are collected in 115 tables. The work is illustrated with 192 cuts and is furnished with a good index. Its size well adapts it to be a handy pocket book of reference, and it is likely to prove of considerable use.

Poisonous Plants of all Countries. By A. B. Smith. Pp. xvi+88. (Bristol: J. Wright and Co., 1905.) Price 2*s*. 6*d*. net.

THE author has collected a fairly representative list of poisonous plants, which he has arranged according to the action produced and the organs affected, but there is no mention made of the part or parts of the plant which furnish the poison. The descriptions, which form the main part of the text, are sufficient where reference is made to the whole plant, but the majority are too meagre to be diagnostic. The string of vernacular names which is quoted in several cases does not serve any useful purpose, whereas beyond the mere name of the toxic principle information which is much required is not given.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Constant of Radiation as Calculated from Molecular Data.

IN NATURE, May 18, I gave a calculation of the coefficient of complete radiation at a given absolute temperature for waves of great length on principles laid down in 1900, and it appeared that the result was eight times

as great as that deduced from Planck's formula for this case. In connection with similar work of his own, Mr. Jeans (*Phil. Mag.*, July) has just pointed out that I have introduced a redundant factor 8 by counting negative as well as positive values of my integers ξ, η, ζ.

I hasten to admit the justice of this correction. But while the precise agreement of results in the case of very long waves is satisfactory so far as it goes, it does not satisfy the wish expressed in my former letter for a comparison of processes. In the application to waves that are not long, there must be some limitation on the principle of equi-partition. Is there any affinity in this respect between the ideas of Prof. Planck and those of Mr. Jeans?

Terling Place, Witham, July 7. RAYLEIGH.

Proposed Observation of Mercury during the Solar Eclipse.

DURING the eclipse of the sun on August 30 next there will be an opportunity of making a very interesting observation on the planet Mercury, to which I ask permission to direct attention.

Mercury at the time of the eclipse will be very close to the line joining the earth and sun—about 2° 54′ south and 2° 54′ preceding the sun—*i.e.* at an angular distance from the sun's centre of nearly 4° 6′. Accordingly, the illuminated part of Mercury will be an excessively thin crescent which, if Mercury have an atmosphere, will have its horns prolonged by atmospheric refraction.

If a sufficiently skilled observer is provided with a telescope upon which he can use a power of 200 without loss of definition, and mounted—probably as an alt-azimuth—so that it can be set beforehand upon Mercury, the apparent size of Mercury will be that which would be presented by a circle one-tenth of an inch across, viewed with the naked eye from a distance of ten inches.

This ought to be sufficient magnification to see whether the horns of the crescent are prolonged, and, if so, it is perhaps not impossible that the light would be sufficient to enable a spectrum of the tips of the crescent to be seen.

If the whole of this programme can be carried out, we should find out whether Mercury has an atmosphere, and possibly learn something as to the constituents of the atmosphere. G. JOHNSTONE STONEY.

30 Ledbury Road, W., July 10.

The Planet Uranus.

ASTRONOMICAL amateurs will have an excellent opportunity of identifying Uranus on about July 16 next, for the planet will be in conjunction with the star 1 Sagittarii (mag. 5·3) on the night following that date.

The position of Uranus at transit (10h. 30m.) will be :—

R.A. 18h. 5m. 58s., Dec. S. 23° 42′ 21″,

while that of the star will be (1905·5) :—

R.A. 18h. 5m. 57s., Dec. S. 23° 43′ 16″,

so that the planet will pass about 1 minute of arc north of the star. The latter may be easily picked up, as it is nearly 4° S. of the triple star μ or 13 Sagittarii (mag. 4·1).

Unfortunately, the objects will be low in altitude (15°), and the moon happens to be full on the date of conjunction.

On June 24 and July 8 I found Uranus a little fainter than the star 1 Sagittarii. I have carefully observed the planet on several nights in a 12½in. Calver reflector, powers 100 to 475. The disc appeared faint with a bluish tinge, and no belts or other markings could be detected, but the telescope is too small to deal effectively with an object of this description.

Bristol, July 9. W. F. DENNING.

The Exploration of the Atmosphere above the Atlantic.

A PLAN for systematic work of this kind, which was proposed by the writer in 1901 at the Glasgow meeting of the British Association (Report, p. 724) after he had obtained the first observations with kites flown from a Transatlantic steamer, is now being partially realised. Last summer Prof. Hergesell, on board the Prince of Monaco's steam-yacht *Princess Alice*, executed sixteen kite-flights above that part of the Atlantic bounded by Spain, the Canaries and the Azores, but without finding the expected south-west anti-trade, although a height of nearly 15,000 feet was reached (NATURE, vol. lxxi. p. 467). The present expedition, which will repeat Prof. Hergesell's investigations and continue them further south, is made possible through the cooperation of our distinguished French colleague, M. Teisserenc de Bort, whose steam-yacht *Otaria*, of 350 tons, with a speed of 11 knots, and fully equipped for aërial exploration, has just sailed from Gibraltar, and, at the joint expense of her owner and the writer, will proceed towards the equator by way of Madeira, Canary and Cape Verde Islands, making frequent soundings with kites through the trade winds and equatorial calms. By means of the self-recording instruments lifted by the kites, it is expected that there will be ascertained the thermal and hygrometric conditions of the various strata traversed, and the depth and force of the trade wind in the different latitudes. If the kites do not reach the south-west return trade, which has been observed on the Peak of Teneriffe, the vertical range of observation may be increased by liberating hydrogen balloons from Madeira and noting their drift.

Mr. Clayton, meteorologist of the Blue Hill Observatory, left Boston on June 3 to join the *Otaria* at Gibraltar. During his voyage to the Azores on the White Star liner *Romanic* he flew kites, with instruments attached, almost daily to the height of from five-eighths to three-quarters of a mile, thus securing the highest observations in mid-Atlantic, and it is interesting that this was done on June 7, the day appointed for the international observations in the upper air here at Blue Hill and in Europe. In general, the temperature was found to decrease with altitude at less than the adiabatic rate, and the relative humidity to decrease also, but in one ascent there was a rise of temperature with altitude, preceding a change of wind from west to south. A new form of folding kite was employed, and it is encouraging to learn that the heights attained were limited by the length and strength of the wire on the hand-reel, which did not permit more than one of these kites to be attached. On the two days when no flights were made, a following wind became too light on board the steamer to lift the kites, whereas, on the yacht, this condition would have been obviated by simply lying-to, or steaming against the wind.

While the cruise of the *Otaria*, which is to last only six weeks, can hardly do more than elucidate certain questions relating to the high atmosphere in the tropics, it will demonstrate the possibilities and difficulties attending the extensive survey that the writer desires to undertake, and which received the endorsement of the International Meteorological Committee at Southport in 1903.

A. LAWRENCE ROTCH.

Blue Hill Meteorological Observatory, Hyde Park, Mass., U.S.A., June 26.

Ancient Antarctica.

PROF. H. F. OSBORN has said that the demonstration of "the former existence of an Antarctic continent is one of the greatest triumphs of modern science." But even if this be true, everyone must allow that it occurred a very long time ago. This is proved by the great differences that exist between the floras and faunas of the three great southern continents. These differences are much greater than those between the floras and faunas of North America and Eurasia, and consequently the land connections must have been broken up in the south long before they were in the north. We infer the former existence of an Antarctic continent from the existence of granite and foliated schists in South Victoria Land, and evidence that it was formerly connected with northern lands is found in the existence of flightless insects living there in the few patches of mosses and lichens which manage to struggle through the winter. These insects are not flightless through degeneration, but belong to an order which never possessed wings.

It is very improbable that the ancestors of these minute insects were carried or blown to where they are now found; they must have travelled to their present positions by land. That is, the Antarctic continent south of New Zealand and Patagonia must, at some time or other, have joined on to northern lands.

In the islands of the Antarctic Ocean we have further evidence of a former land connection in the earthworms belonging to the family Acanthodrilidæ, which are characteristic of Antarctic regions. A spider also lives on Bounty Islands which is closely related to one from Cape Horn. But spiders seem to have special facilities for crossing barriers, and the insects found on Bounty Islands are all related to New Zealand forms. I do not include here the evidence of the plants of the Antarctic islands, for most plants do not require that the land should be actually continuous to enable them to spread.

But if the flightless insects and the earthworms imply a former connection with northern lands, that connection must have been a very long time ago, before the spread of insects and angiospermous plants over the world, that is, not later than the Jurassic period. If there had been any land connection in Tertiary times, there would have been a much greater mixing of the animals and plants.

It is evident that the flora, and perhaps the fauna, of Antarctica were formerly much richer than at present, as is proved by the fossil plants of South Victoria Land, and it is also probable that both fauna and flora were killed off by an increasingly rigorous climate. It is not necessary to assume a former Glacial epoch for this, for higher plants and animals could hardly resist the present climate, and there is no palæontological evidence of a period of greater cold than now having ever existed in the southern hemisphere. On the contrary, the biological as well as the palæontological evidence is against the idea. For the much modified plover, Chionis, and the insects of Kerguelen Land, as well as the remarkable flora of the Antarctic islands, show that the islands could not have been covered with ice for a very long time.

The relations between the avifaunas of Australia and South Africa are much closer than exist between those of Australia and South America, and this is just what we should expect if the ancestors of the present birds had spread down from the north under the present condition of land and sea, for the land connection between Australia and South Africa is far more intimate than that between the former place and South America. But the contrary is the case with the Mammalia, some of the tortoises, snakes, frogs, some of the fresh-water fishes, a large number of insects, and the family Cryptodrilidæ of earthworms. This implies that at some former time a closer connection existed between Australia and South America than between Australia and Africa. The question is, Was this connection by means of an Antarctic continent? Or was it by a Pacific continent?

The principal objection to the southern route is that the connection between Australia and South America is shown by a number of subtropical animals—such as Osteoglossum and Ceratodus—none of which have left any trace of their passage through New Zealand. We cannot suppose that New Zealand was disconnected at the time from the Antarctic continent, for it, also, has distinct relations with South America, but for the most part by means of different animals from those which show the Australian connection. If the connection was in either the Cretaceous or the Eocene period, we might suppose that the climate was warm enough for the passage of the subtropical animals by the Antarctic route, but, if so, why are there no traces of marsupials and South American frogs in New Zealand? If, on the other hand, we suppose the ancestors of these animals to have crossed from Australia to South America by a South Pacific continent, we can understand how the subtropical forms would not have come so far south as New Zealand, while the New Zealand forms would have crossed at a higher latitude. In favour of this we have a member of the Iguanidæ in Fiji, as well as the evidence of the land shells of Polynesia, which are not a collection of waifs and strays, but form a distinct group of a very early type, which, however, has not yet been found in South America.

We still have to consider the floras and the marine faunas of the Antarctic islands. Here we see a number of birds—such as cormorants and gulls—as well as fishes and plants, which could hardly spread round the world under the present conditions of land and water. That this spreading was a comparatively late one is proved by the near relations between the species. But if there had been continuous land at the time, land animals would have spread with the marine ones. It is therefore necessary to suppose that this last spreading of species in Antarctic latitudes was by means of a number of islands. Probably this was in Pliocene times, if we may judge by the amount of differentiation which has taken place since then.

I therefore conclude that the hypothesis which best explains the phenomena is the following:—

(1) That in the Jurassic period an Antarctic continent existed which connected South America with New Zealand and South Africa.

(2) That this continent sank in the Cretaceous period, and that Antarctica has never since been connected with northern lands.

(3) That in the Cretaceous or early Eocene a Pacific continent connected New Guinea and New Zealand with Chili.

(4) That this land sank at the close of the Eocene.

(5) That in the Pliocene a number of islands existed in the Antarctic Ocean, which have since then disappeared.

F. W. HUTTON.

The British Slugs.

MR. J. W. TAYLOR has just published part ii. of his admirable "Monograph of the Land and Freshwater Mollusca of the British Isles," containing a discussion of the slugs of the genus Arion. It is a matter of interest that, notwithstanding the great amount of information gathered in recent years, the beautiful bicoloured varieties of *A. ater* appear to hold their own as truly endemic inhabitants of Britain. These are three in number, though Mr. Taylor treats the third as merely a subvariety.

(1) *Arion ater*, var. *albolateralis*, Roebuck, 1883. Back black, sides white.

(2) *Arion ater*, var *Roebucki* (*bicolour*, Roebuck, in error). Back brown, sides yellow.

(3) *Arion ater*, var. *Scharffi*, Cockerell, 1893. Back black, sides yellow.

Mr. Taylor retains the name *bicolour* for the second variety, but it is not the *bicolour* of Moquin-Tandon, as was formerly supposed, and a new name is necessary. It is appropriate to name it after Mr. Roebuck, who first made it known. These magnificent slugs are of western distribution in the British Islands, and have quite a wide range. The only evidence of their occurrence on the Continent is Scharff's statement that Simroth found specimens "similar" to var. *Roebucki* on the shores of the Baltic; and the possibility that the Norwegian var. *medius*, Jensen, may be similar to *albolateralis*, though it is very likely not even of the same species. A quite different variety of *A. ater* is the wholly black form *aterrima*, said to be especially northern and montane. According to Mr. Taylor, this is exclusively British, except that it appears to be represented in Spain and Portugal by a similar animal named *hispanicus* by Simroth. However, I had always regarded this *aterrima* variety as the one so described from France by Dumont and Mortillet (*cf. Science Gossip*, 1889, p. 212, "the pitchy black variety found in swamps"), and if it is not, the name *aterrima*, applied to it by Mr. Taylor, cannot stand. At the opposite pole of variation from *aterrima* is the brilliant red form *A. ater*, var. *coccinea* (Gistel), which is hardly ever found in England, but is abundant in the warmer and drier regions of Central Europe.

Incidentally, it may be remarked that the name *Arion hortensis*, var. *subfusca*, employed by Mr. Taylor, cannot be retained, as it is founded on *Limax subfuscus*, C. Pfr., a homonym of *L. subfuscus*, Draparnaud.

University of Colorado, June 26.

NOTES ON STONEHENGE.[1]

VII.—ON THE DARTMOOR AVENUES.

SOME years ago I referred in NATURE to the numerous alignments of stones in Brittany, and I was allowed by Lieut. Devoir, of the French Navy, to give some of his theodolite observations of the directions along which the stones had been set up.

The conclusion was that we were really dealing with monuments connected with the worship of the sun of the May year, a year which the recent evidence has shown to have been the first recognised after the length of the year had been determined; thus replacing the lunar unit of time which was in vogue previously, and the use of which is brought home to us by the reputed ages of Methuselah and other biblical personages, who knew no other measurer of time than the moon.

There was also evidence to the effect that in later times solstitial alignments had been added, so that the idea that we were dealing with astronomically oriented rows of stones was greatly strengthened, not to say established.

So long as the Brittany alignments were things of mystery, their origin, as well as that of the more or less similar monuments in Britain, was variously explained; they were models in stone of armies in battle array, or they represented funeral processions, to mention only two suggestions. I should add that Mr. H. Worth, who has devoted much time to their study, considers that some sepulchral interest attaches to them, though he thinks it may be argued that that was secondary, even as are interments in cathedrals and churches. About burials associated with them, of course, there is no question, for the kistvaens and cairns are there; but my observations suggest that they were added long after the avenues were built, as some cairns *block* avenues. Perhaps a careful study of the mode of burial may throw light on this point.

The equivalents of the Brittany alignments are not common in Britain; they exist in the greatest number on Dartmoor, whither I went recently to study them. The conditions on high Dartmoor are peculiar.

Blinding mists are common, and, moreover, sometimes come on almost without warning. From its conformation the land is full of streams. There are stones everywhere. What I found, therefore, as had others before me, was that as a consequence of the conditions to which I have referred, directions had been indicated by rows of stones for quite other than ceremonial purposes. Here, then, was a possible third origin. It was a matter of great importance to discriminate most carefully between these alignments, and to endeavour to sort them out. My special inquiry, of course, was to see if they, like their apparent equivalents in Brittany, could have had an astronomical origin. The first thing to do, then, was to see which might have been erected for worship or which for practical purposes.

In doing this there is no difficulty in dealing with extremes. Thus one notable line of large flat stones has been claimed by Messrs. R. N. Worth and R. Burnard as a portion of the Great Fosseway (Rowe's "Perambulation," third edition, p. 63); it has been traced for eighteen miles from beyond Hameldon nearly to Tavistock, the stones being about 2 feet thick and the road 10 feet wide.

There are two notable avenues of upright stones at Merrivale; they are in close connection with a circle, and could have had no practical use. These stones, then, we may claim as representing the opposite extreme of the Fosseway and as suggesting an astronomical, as opposed to a practical, use; the adjacent circle, of course, greatly strengthens this view.

It is between these extremes that difficulties may arise, but the verdict can, in a great many cases at all events, be settled without any very great hesitation, especially where practical or astronomical uselessness can be established. But even here care is necessary, as I shall show.

The stones now in question, originally upright, are variously called avenues, rows, alignments or parallelithons. Their study dates from 1827, when Rowe and Colonel Hamilton Smith examined those at Merrivale (Rowe, *op. cit.*, p. 31). Their number has increased with every careful study of any part of the moor, and doubtless many are still unmapped.[1] The late Mr. R. N. Worth, of Plymouth, and his son, Mr. H. Worth, have given great attention to these monuments, and the former communicated a paper on them to the Devonshire Association for the Advancement of Science in 1892 (Trans., xxv. pp. 387–417).

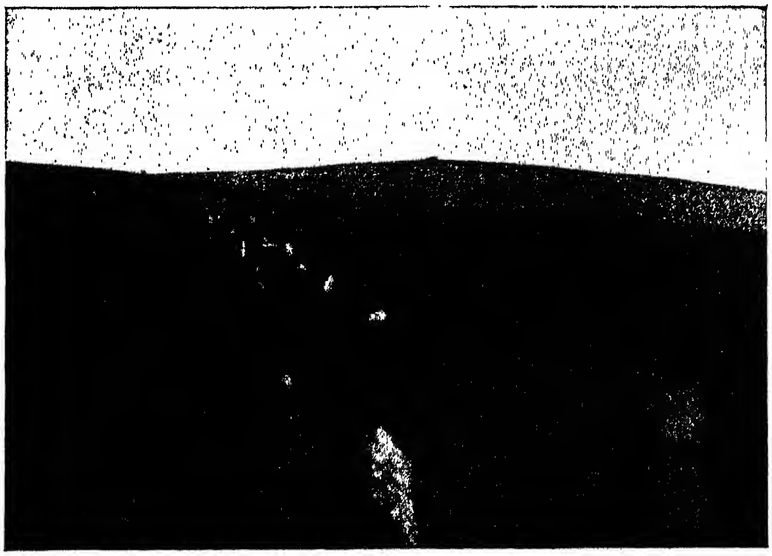

Photo. by Lady Lockyer.

FIG. 17.—The Southern Avenue at Merrivale, looking East.

A word of caution must be said before I proceed. We must not take for granted that the stone-rows are now as they left the hands of the builders. The disastrous carelessness of the Government in the matter of our national antiquities is, I am locally informed, admirably imitated by the Devonshire County and other lesser councils, and, indeed, by anybody who has a road to mend or a wall to build. On this account, any of the rows may once have been much longer and with an obvious practical use; and

[1] Continued from p. 34.

[1] Only yesterday (June 15) that excellent guide of the Chagford part of the moor, Mr. S. Perrott, showed me an avenue (Azimuth N. 20° E. true) near Hurston Ridge which is not shown in the 1-inch map.

those which now appear to be far removed from circles may once have been used for sacred processions at shrines which have disappeared.

Again, the rows of stones we are now considering must not be confounded with the "track lines" or "boundary banks" which are so numerous on Dartmoor and are represented in Wiltshire according to Sir R. C. Hoare; these serve for bounds and pathways, and for connecting and enclosing fields or houses.

Dealing, then, with stone rows or avenues, which may be single, double, or multiple; any which are very long and crooked, following several directions, are certainly not astronomical; and it is easy to see in some cases that they might have been useful guides at night or in mist in difficult country with streams to cross. This possible utility must not be judged wholly by the present conformation of the ground or the present beds of streams.

For multiple avenues it is hard to find practical uses such as the above, and we know how such avenues were used in Brittany for sun worship. Mr. Baring Gould considers there were eight rows in an avenue on Challacombe Down 528 feet long; of these only three rows remain, the others being represented by single stones here and there (Rowe, p. 33). I shall have something to say about this avenue further on.

Although, as I have said, long rows bending in various directions are not likely to have had an astronomical origin, it must not be assumed that all astronomical avenues must be *exactly* straight. This, of course, would be true for level ground, but if the avenue has to pass over ridges and furrows, the varying height of the horizon must be reckoned with, and therefore the azimuth of the avenue at any point along it.

I think it possible that in the Staldon Moor row we have the mixture of religious and practical intention at which I have before hinted. Both Mr. Lukis and Mr. Hansford Worth have studied this monument, which is two miles and a quarter long. There is a circle at the south end about 60 feet in diameter, while at its northern end there is a cairn.

Where the line starts from the circle the direction of the row is parallel to many sight-lines in Cornwall, and Arcturus would rise in the azimuth indicated. But this direction is afterwards given up for one which leads towards an important collection of hut circles, and it crosses the Erme, no doubt at the most convenient spot. More to the north it crosses another stream and the bog of Red Lake. All this is surely practical enough, although the way indicated might have been followed by the priests of the hut circles to the stone circle to prepare the morning sacrifice and go through the ritual.

But there is still another method of discrimination. If any of these avenues were used at all for purposes of worship, their azimuths should agree with those already found in connection with circles in other parts of Britain, for we need not postulate a special race with a special cult limited to Dartmoor; and in my inquiries what I have to do is to consider the general question of orientation wherever traces of it can be found. The more the evidences coincide the better it is for the argument, while variations afford valuable tests.

Now, speaking very generally (I have not yet compared all my numerous notes), in Cornwall the chief alignments from the circles there are with azimuths N. 10°–20° E. watching the rise of Arcturus, N. 24°–28° E. watching the rise of the May sun, N. 75°–82° E. watching the rise of the Pleiades. The variation in the azimuths is largely due to the different heights of the horizon towards which the sight-lines are directed.

The conclusion I have come to is that these alignments, depending upon circles and menhirs in Cornwall, are all well represented on Dartmoor associated with the avenues; and further, so far as I have learned at present, in the case of the avenues connected with circles, there are not many alignments I have not met with in connection with circles in Cornwall and elsewhere.

This is not only a *prima facie* argument in favour of the astronomical use underlying the structures, but it is against the burial theory, for certainly there must have been burials in Cornwall.

In order, therefore, to proceed with the utmost caution, I limit myself in the first instance to the above azimuths, and will begin by applying a test which should be a rigid one.

If the avenues on Dartmoor had to deal with the same practices and cults as did the circles in Cornwall, they ought to prove themselves to have been in use at *about* the same time, and from this point of view the investigation of the avenues becomes of very great importance, because of the destruction of circles and menhirs which has been going on, and is still going on, on Dartmoor. We have circles without menhirs and menhirs without circles, so that the azimuths of the avenues alone remain to give us any chance of dating the monuments if they were used in connection with sun worship. The case is far different in Cornwall, where both circles and menhirs have in many cases been spared.

On Dartmoor, where in some cases the menhirs still remain, they have been annexed as crosses or perhaps as boundary stones, and squared and initialed; hence the Ordnance surveyors have been misled, and they are not shown as ancient stones on the map. In some cases the azimuth of the stones suggests that this has been the sequence of events.

It will be seen from the above that I have not tackled a question full of pitfalls without due caution, and this care was all the more necessary as the avenues have for long been the meeting ground of the friends and foes of what Rowe calls "Druidical speculations"; even yet the war rages, and my writing and Lieut. Devoir's observing touching the similar but grander avenues of Brittany have so far been all in vain; chiefly, I think, because no discrimination has been considered possible between different uses of avenues, and because the statements made by archæologists as to their direction have been quite useless to anybody in consequence of their vagueness, and last of all because the recent work on the Brittany remains is little known.

I began my acquaintance with the Dartmoor monuments by visiting Merrivale, and the result of my inquiries there left absolutely no doubt whatever on my mind. I was armed, thanks to the kindness of Colonel Johnston, the director of the Ordnance Survey, with the 25-inch map, while Mr. Hansford Worth had been so good as to send me one showing his special survey.

The Merrivale avenues (lat. 50° 33′ 15″) are composed of two double rows, roughly with the azimuth N. 82° E.; the northern row is shorter than the other. Rowe, in his original description (1830), makes the northern 1143 feet long; they are not quite parallel, and the southern row has a distinct "kink" or change of direction in it at about the centre. The stones are mostly 2 or 3 feet high, and in each row they are about 3 feet apart; the distance between the rows is about 80 feet.

I have before pointed out that an avenue directed to the rising place of a star, if it is erected over undulating ground, cannot be straight. I may now mention another apparent paradox. If two avenues are directed to the rising place of the same star *at different times*, they cannot be parallel. It is not a little curious that absence of parallelism has been used against avenues having had an astronomical use!

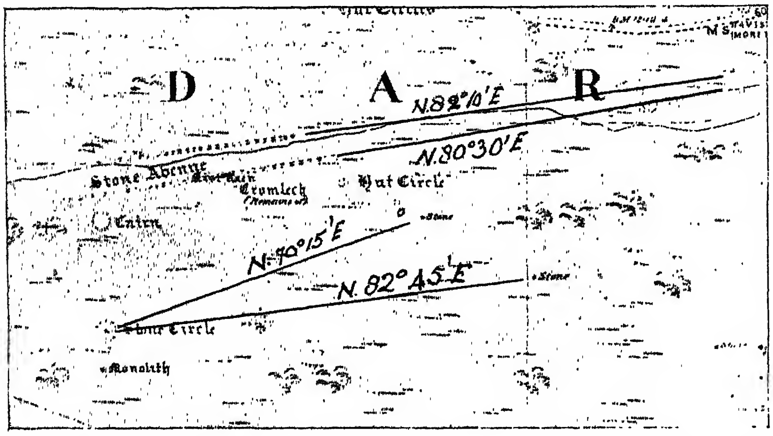

FIG. 18.—Plan, rom the Ordnance Map, showing the avenues, circle and stones at Merrivale, with their azimuths.

Both the Ordnance surveyors and Mr. Worth have shown the want of parallelism of the two avenues, and Mr. Worth has noted the kink in the southern one. The height of the horizon, as determined from my measures, is 3° 18′. The results of these inquiries, assuming the Pleiades to have been observed warning May morning, are as follows:—

Azimuth	Authority	N. Declination ° ′ ″	Date B.C.
N. 83·15 E.	Worth	6 47 47	1710
82·30	Worth	7 16 20	1630
82·10	Ordnance	7 32 0	1580
80·40	Worth	8 26 0	1420
80·30	Ordnance	8 30 0	1400

To simplify matters we may deal with the Ordnance values and neglect the small change of direction in the southern avenue. We have, then, the two dates 1580 B.C. and 1420 B.C. for the two avenues. The argument for the Pleiades is strengthened by the fact that at Athens the Hecatompedon was oriented to these stars in 1495 B.C. according to Mr. Penrose's determination of the azimuth.

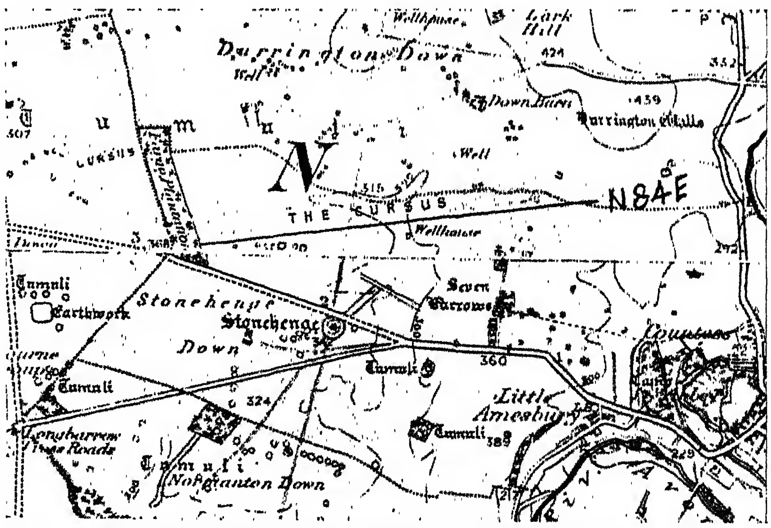

FIG. 19.—Reprint of Ordnance Map showing that the Cursus at Stonehenge is nearly parallel to the Merrivale Avenue. The azimuth is 82° and not 84° as shown in the figure.

Now this is not the first time I have referred to avenues in these notes. The azimuth of one at Stonehenge was used to fix the date at which sun worship went on there. That avenue, unlike the Dartmoor ones, was built of earth, and it is not alone. There is another nearly two miles long called the Cursus. So far, I have found no solstitial worship on Dartmoor, so there are no avenues parallel to the one at Stonehenge leading N.E. from the temple. But how about the other? *It is roughly parallel to the avenues at Merrivale, and I think, therefore, was, like them, used as a processional road, a via sacra, to watch the rising of the Pleiades.*

I said roughly parallel; its azimuth is about the same (N. 82° E. roughly); but the horizon is only about 1° high; it was therefore in use before those at Merrivale; the exact date of use must wait for theodolite values of the height of the horizon, but in the meantime we can see from the above estimates that the declination of the Pleiades was about N. 5° 28′ 30″ and the date of use 1950 B.C., that is some 300 years before the solstitial restoration.

Mr. Worth's survey gives another line of stones which is not shown in the Ordnance survey. It is undoubtedly, I think, an ancient line, although it is not shown in the Ordnance map, a clear indication of the difficulty of discriminating these avenues on land cumbered with stones in all directions. Its azimuth is N. 24° 25′ E., and the height of the horizon 5° 10′. This gives us Arcturus at the date 1860 B.C., showing that, as at the Hurlers, Arcturus was used before the Pleiades. Hence a possible *astronomical* use is evident, while this row, like the others, could have been of no *practical* use to anybody. It is interesting to note that this single row of stones is older than the double ones; this seems natural.

It is worth while to say a word as to the different treatment of the ends of the south avenue now that it seems probable that it was used to watch the rising of the Pleiades. At the east end there is what archæologists term a "blocking stone"; these observations suggest that it was really a *sighting* stone. At the west end such a stone is absent, but the final stones in the avenue are longer than the rest. This may help us to determine the true direction of the sight-lines in other avenues, and, indeed, I shall show in the sequel that it affords a criterion which in some cases is entirely in harmony with other considerations.

NORMAN LOCKYER.

SOLAR AND TERRESTRIAL CHANGES.

THE problem of the relations between sun-spots and other solar phenomena and weather has engaged the attention of men of science for many years past. The results of their investigations have not, perhaps, been so satisfactory or conclusive as were at first anticipated, but this, fortunately, has not diminished the enthusiasm of those interested in the solution of the problem. The ordinary public who were attracted by the apparent simplicity and probability of the relations suggested have undoubtedly been disappointed with the results. There has hence been a tendency for some time past to depreciate investigation in this field of science. On the other hand, the experience of the recent droughts and famines in India, Australia, and South Africa has directed attention strongly to the probable relation between variations of solar activity and the larger variations of rainfall over the earth's surface. The aqueous vapour precipitated as rain over large land areas such as India is produced by evaporation over distant oceanic areas, and is thence carried to the areas of discharge by the larger atmospheric currents. These actions are the direct results of the conversion of solar energy, and any large variation in the supply of that energy must be accompanied with, and followed by, corresponding changes in the amount of evaporation and atmospheric movement, and hence, also, of amount and distribution of rain. The determination of the relations thus indicated is not merely of value from the scientific standpoint, but has important practical bearings, as it may lead to a satisfactory method of long-period weather forecasting —a question which is largely engaging the attention of meteorologists at the present time.

Three lines of observation (and hence also of investigation) carried on at the present time furnish data for the solution of the problem. These are the observations of terrestrial magnetism, of terrestrial atmospheric meteorology, and of solar phenomena.

A large number of magnetic observatories, furnished with the most delicate and sensitive instruments, provide a continuous record of the changes of the earth's magnetic state by its action on magnetised needles at the earth's surface.

The work of meteorological observation has made great progress during the past twenty-five years. It has not only been extended and improved, but is carried on much more systematically than hitherto. Unfortunately its record is very imperfect, as it is probably not too much to say that over at least five-sixths of the earth's surface, including the greater part of the interior of Asia and Africa, and over the larger oceanic areas and the Polar regions, the amount of observation is exceedingly small and of little value for the solution of the problem. There is hence a continuous record of the meteorological changes of the earth's atmosphere over barely one-sixth of its surface. There is, moreover, no general collection and publication of the meteorological data in such a form as to give a continuous history of the larger atmospheric variations and changes in progress over even that sixth part of the earth's surface.

The third branch of observation, that of solar phenomena, has made wonderful progress during the past fifty years. Previously the telescopic examination of the sun's surface had disclosed the eleven-year periodicity of the sun-spots. Latterly the combination of the spectroscopic and telescopic observation of the sun has revealed the complexity of the changes in progress throughout the depth of its atmosphere, and of which the sun-spots are only one and a very partial expression. This field of investigation is so promising that solar observatories have been established in many countries, and a continuous record of the solar changes, so far as they are indicated by present methods of observation, is now possible by combining the data furnished by all the observatories. The work of correlating the three classes of observation has, however, not yet been commenced in a systematic manner, although the necessity is now fully recognised.

It is now generally, if not universally, admitted that the sun is practically the sole source of the energy which maintains the movements of the earth's atmosphere. It is the centre of a continuous outflow of radiant energy, a very small portion of which is intercepted and appropriated by the earth, where it is converted into other forms of energy. The investigation of the rate of this flow of energy and its time variations, the analysis of the total energy into its elements as that of a series of oscillatory movements of different periods and amplitudes or wavelengths, and the problem of its distribution in its passage through the atmosphere and at the earth's surface are each in little more than the initial stages. In some departments of the investigation, as, for example, the laws of the absorption of the solar energy during its passage through the earth's atmosphere, much work has been done, but with comparatively little result.

The appropriation of solar energy by the earth affects it mainly in two ways, first, as a whole, determining or modifying its magnetic condition, and secondly, partially, affecting the atmosphere and a thin surface layer of the solid or liquid mass. Any variation in the flow of solar energy, periodic or irregular, will theoretically give rise to corresponding changes in the earth's magnetic condition and its atmospheric movements. The determination of the relations between the three classes of variation is on the whole the most important problem in this field of inquiry into the solar energy and its variations and effects.

The first part of the problem, that is, the relation of the variations of solar energy (as manifested and measured by the observable changes in the number and extent of the sun-spots, prominences, &c.) to those of the magnetic condition of the earth shown by its action on a magnetised needle suitably suspended, is comparatively simple, as the earth appears to be similarly affected as a whole and throughout its whole mass. The variations are indicated as clearly and satisfactorily by an observatory in India or Australia as at Kew in England. There are undoubtedly local variations which may require to be eliminated in order to obtain the general variation. It has, however, been conclusively established by observations in different regions that there is a general parallelism between the amount and extent of the magnetic variation or disturbance and the number and magnitude of the sun-spots and prominences. The rule is, the larger the number of sun-spots the greater the amount of the magnetic variation and disturbance. The relation can, however, at the present stage only be considered as statistical, as it has not been established for single sun-spots. In other words, the observed outburst or sudden appearance of a single spot or prominence is not invariably accompanied by a terrestrial magnetic disturbance. Various reasons have been given for the failure of parallelism in detail. Hence all that can be inferred at the present time is that definite relations (of a statistical kind) of great importance have been obtained which more than justify the continuance of this branch of the inquiry, and make it desirable that the work of terrestrial magnetic observation and investigation, and of comparison with solar phenomena, should be maintained and if possible extended.

Numerous attempts, only very partially successful, have been made to establish similar definite relations between solar and terrestrial atmospheric variations. The South Kensington observatory has done much valuable work in this direction. It is, however, doubtful whether the results obtained by any of the investigators in this branch are generally accepted.

The reasons for this very partial success are almost self-evident, and are due to the complexity of the problems presented by the movements of the atmosphere, more especially as modified by the presence of very varying amounts of aqueous vapour, the result of the processes of evaporation and condensation. The effects of the solar variation on the earth's atmosphere are, in fact, distributed and manifested in very varying proportion between the different elements of observation, and the direct effect of a solar variation on one element may be followed by an opposite effect due to variation of another element, so that the final result may be opposite in character to the initial effect. Thus an increase of solar radiant energy would, if there were no increase of aqueous vapour amount, cloud or air movement, undoubtedly increase pressure and temperature. If these changes, however, give rise to increased vertical and horizontal movement, it is possible that as a later result pressure probably, and temperature possibly, might both be decreased below their original or normal level, and hence that the observed change might be the opposite to that of the direct effect of the original variation. Also there is another source of difficulty in this branch of the inquiry, due to the fact that in the case of some of the elements of observation a positive variation over a considerable area of the earth's surface must necessarily be accompanied with a negative variation of corresponding amount in some other region as part and parcel of the total change. The changes in these elements, taken over the earth's surface, must either be completely compensatory, as is probably the case for pressure, or partially compensatory, as is undoubtedly the case for rainfall.

It is also necessary to bear in mind that the instrumental appliances for magnetical and meteorological observations are of very different orders of exactness. Magnetic instruments, more especially those for continuous autographic registration, are of great delicacy. Meteorological instruments are, on the other hand, much less delicate, and the most important of all from certain points of view, viz. the instruments for registering the direction and rate of air movement, are especially coarse, and their individual observations are necessarily affected with large errors.

The problem of the relations between solar and terrestrial meteorological variations is hence complicated and difficult. It evidently requires for its complete solution the collection and coordination of data for the whole of the earth's surface, and the careful employment of statistical methods regulated by thorough knowledge of the physics of the atmosphere.

The difficulties of the problem are great, and explain the comparative want of success of investigators hitherto. It is, however, certain from theoretical considerations that there are definite relations, and that their determination is of great importance, equally from the scientific and the utilitarian point of view.

The observational data for a more systematic investigation are now considered by many to be sufficient, if collected, compared, and discussed as a whole, to promise more satisfactory and valid conclusions than have hitherto been obtained, and perhaps a first approximate solution. This opinion found expression fully at the meeting of the British Association at Southport in 1903. Sir Norman Lockyer, director of the Solar Physics Observatory, South Kensington, read a report giving a summary of the results of previous investigations in "Simultaneous Solar and Terrestrial Changes" to Section A of the British Association. The members of the International Meteorological Committee present at the meeting joined in the discussion, and it was decided that the time had arrived for joint and concerted action. A commission to act as a subcommittee of the International Meteorological Committee was formed to discuss meteorological observations from the point of view of their connection with magnetism and solar physics. The commission held several meetings at Cambridge in 1904 during the British Association week. Several additional members were added to the commission, which now includes the names of the leading authorities in the three associated branches of science.

The chief work of the commission at Cambridge was to lay down principles for the selection of the data required for comparison, and to arrange for the choice of stations and observatories from which it would be desirable to obtain data prior to entering into communication with the various organisations that it would be necessary to ask for assistance in the collection of data.

It has been arranged that a meeting of the commission shall be held in connection with the meeting of the International Meteorological Committee at Innsbruck in September. A number of important matters will there be considered. Amongst these are the final selection of magnetic and meteorological observatories from which data are to be collected, the mode of publication of the data received by the commission, and probably, also, of the methods to be employed in the work of comparison and discussion of the data. Hofrath Prof. Julius Hann has suggested for consideration a method of determining the variation of temperature during a sun-spot period. This will, it is hoped, lead to an interesting discussion on the methods of investigation most suited and appropriate for the determination of the relations between solar and terrestrial phenomena.

THE PROPOSED COLLEGE OF APPLIED SCIENCE.

THE appearance of the preliminary report of the Departmental Committee on the Royal College of Science and Royal School of Mines, which was published in our issue of last week, brings us an important step nearer the realisation of an object after which men of science have long striven; the provision, that is, of a great metropolitan college—liberally endowed, handsomely housed, adequately equipped, and generously staffed—designed amply to supply that higher technical instruction for which there has been little provision hitherto, but upon which our well-being as a commercial and manufacturing nation ultimately depends.

The report shows that the committee has been engaged wisely in determining what precisely the existing facilities for instruction in applied science are, and in gathering the information necessary to decide what the new college should supply in addition to these, so as to place London, as the centre of the Empire, in a condition to compare educationally with Berlin, for example, or with many great American cities. It is unnecessary here to recapitulate the recommendations of the committee, but the special wisdom of

one or two of its conclusions cannot be insisted upon too earnestly or too often.

The new institution must be in no sense parochial, nor must it be allowed to become merely metropolitan. From the beginning the design must be to give the college an Imperial character, and every means must be taken to encourage young men possessed of the necessary qualifications, in whatever part of the Empire they may be, to attend its courses and avail themselves of the means offered by it of becoming familiar with recent advances in technology and with any branch of applied science in its highest form.

The new institution must not be allowed to become merely another technical college on a larger scale—of technical institutes we have many already. The "duly qualified students" referred to by the committee should have already received collegiate training, and have taken a degree. To quote the report:—"Admission to these higher courses should be restricted to duly qualified students who, it is hoped, would be attracted from all parts of the Empire." The public must be taught to estimate the success of the new institution, not by the number of its roll-call, but by the number of expert engineers of all kinds, of original technical chemists, of machine designers, and so on, who are trained within its portals.

But besides being able to supply the future manufacturer with the very latest results from the research laboratories of workers outside its walls, the new institution, if it is to be really successful, must itself be an active centre of research. As the report says:—"It is of the first importance that there should be no divorce between teaching and research in technology on the one hand and in pure science on the other," and the new college must be as notable for its success in research in technology as for the ability possessed by its staff to acquaint the student with the findings of recent scientific work. Unless from the beginning the student feels he is under the influence of professors who are not only familiar with all the conditions of actual manufacture in its most successful form, but who are responsible also for the improvements in technical processes which win success, the institution will neither do the work expected of it nor win the confidence of our manufacturing magnates and merchant princes. Only that science—whether pure or applied—really lives which grows continually, and such growth without patient research is impossible. The new institution must above all things be the growing point of our national system of technical instruction.

To fulfil these two functions—on which the report rightly lays very great emphasis—the staff of the Imperial college must be both numerous and the best available. In other words, the institution must of necessity be a costly one, judged, that is, from the standard adopted previously in this country for estimating educational expenses. But if properly selected such a staff will very soon show, by the results accomplished, that generous expenditure on higher education is a remunerative form of national expenditure. It is gratifying to find from the report that there is every prospect that a sufficient revenue will be eventually forthcoming, in the provision of which funds the State will take its part. We learn from the *Times* that the Government has decided to allocate 20,000*l.* a year to the college out of the Treasury subsidy for the maintenance of the Royal College of Science and the Royal School of Mines, and that an intimation to this effect has been made by the Chancellor of the Exchequer to Mr. Haldane, the chairman of the Departmental Committee.

There is every reason to hope that London will ere long have at South Kensington a college of applied science which will be as much admired as the similar institution at Charlottenburg, and prove as useful to the industries of this country as the Berlin college has to those of Germany.

NOTES.

As the new buildings of the University of Sheffield were opened by the King at the time the present issue of NATURE was being prepared for press, we cannot do more than record the fact, reserving a description of the buildings and an account of the opening ceremony for a subsequent number.

THE annual meeting of the Imperial Cancer Research Fund was held on July 5 at Marlborough House, the Prince of Wales presiding. Sir William Church moved the adoption of the secretary's, superintendent's, and treasurer's reports, which was seconded by Mr. Tweedy. Mr. Henry Morris moved that the best thanks of the meeting be given to His Royal Highness for presiding, which was carried with acclamation. The Prince of Wales in reply alluded to the researches which had been carried out in the laboratories of the fund, and expressed his satisfaction that the committee had again secured the services of Sir William Church as chairman of the executive committee.

THE summer show of the Royal Horticultural Society was opened on Tuesday last, and will remain open until this evening. It is being held for the first time in the grounds of Chelsea Hospital. The society appears to be in a very flourishing condition, more than 1000 new fellows having been added within the last few months.

THE Albert medal of the Society of Arts for 1905 was, on Wednesday, July 5, at Marlborough House, presented by the Prince of Wales, as president of the society, to Lord Rayleigh "in recognition of the influence which his researches, directed to the increase of scientific knowledge, have had upon industrial progress, by facilitating, amongst other scientific applications, the provision of accurate electrical standards, the production of improved lenses, and the development of apparatus for sound signalling at sea."

THE French Association for the Advancement of Science will this year meet at Cherbourg. The session will extend from August 3 to 10.

THE summer meeting of the Institution of Naval Architects will take place on July 19, 20, and 21 in the hall of the Society of Arts. The following papers will be read and discussed:—"Tactics and Strategy at the Time of Trafalgar," by Admiral Sir Cyprian Bridge, G.C.B.; "The Ships of the Royal Navy as they Existed at the Time of Trafalgar," by Sir Philip Watts, K.C.B., F.R.S., vice-president; "The Classification of Merchant Shipping, illustrated by a Short History of Lloyd's Register," by H. J. Cornish; "Experiments with Models of Constant Length and Form of Cross Sections, but with varying Breadths and Draughts," by Lieut.-Col. B. Rota; "Experiments on the Effect of Depth of Water on Speed, having Special Reference to Destroyers recently Built," by H. Yarrow; "Deductions from Recent and Former Experiments on the Influence of the Depth of Water on Speed," by W. W. Marriner; "The Failure of some large Boiler Plates," by J. T. Milton; and "A Comparison of the Performances of Turbines and Reciprocating Engines in the Midland Railway Company's Steamers," by W. Gray.

The London congress of the Royal Institute of Public Health will be held from Wednesday next, July 19, to Tuesday, July 25, under the presidency of Sir James Crichton Browne. The meetings will take place at King's College, Strand, and at the Polytechnic, Regent Street. In connection with the congress there will be an exhibition of sanitary and educational appliances at the Regent Street Polytechnic, and this will remain open until July 28.

The *British Medical Journal* announces that a tuberculosis exhibition, arranged under the auspices of the National Association for the Study and Prevention of Tuberculosis, and of the Committee on the Prevention of Tuberculosis of the Charity Organisation Society, will be held in New York in November next. The object of the exhibition is the education of the people. In addition to exhibits illustrating different phases of the tuberculosis problem, and especially the treatment of the disease, popular lectures will be delivered by specialists.

The Long Fox memorial lecture for this year will, says the *Lancet*, be delivered in November by Dr. E. Markham Skerritt.

M. Curie was last week elected a member of the Paris Academy of Sciences.

The Mary Kingsley medal of the Liverpool School of Tropical Medicine has been awarded to Dr. Laveran, of the Pasteur Institute, Sir Patrick Manson, K.C.M.G., F.R.S., and Col. Sir D. Bruce, K.C.B., F.R.S.

Lord Kelvin and Sir William Christie, Astronomer Royal, were at the final meeting of the present session of the Optical Society made honorary members of the society.

It is stated in *Science* that Prof. William Osler has been made honorary professor of medicine at the Johns Hopkins University.

The president of the Board of Agriculture (the Right Hon. Ailwyn E. Fellowes) will distribute the diplomas and prizes at the South-eastern Agricultural College, Wye, on Friday, July 21.

We learn from the Royal Society that as an adjunct to the International Laboratory of Physiology on Monte Rosa, a lower laboratory, with a hostel, has been established at Col d'Olen. This lower laboratory is mainly intended for biological research, but it is understood that provision has also been made for the study of terrestrial physics and meteorology. The Royal Society has the permanent nomination to two posts, each of which includes a living room in the hostel, a bench in the laboratory, and the use of apparatus; but the expenses of living and of special researches must be borne by the investigators. The laboratory is especially connected with the University of Turin, but is under the immediate direction of a committee. Applications for nominations to the two posts referred to above may be addressed to the secretaries of the Royal Society, Burlington House, London, W.

A Reuter telegram from Florence states that the instruments of the Delle Quercie Observatory of that place recorded on Sunday last severe earthquake shocks as taking place in a distant country.

The death is announced from Belgium of M. Elisée Reclus, the French geographer, in his seventy-sixth year. At the University of Berlin he studied under the great geographer Karl Ritter. Having in 1851, because of his political opinions, to leave France, he travelled for six years, visiting England, Ireland, North America, Central America, and Colombia. Returning to his native country in 1857, he contributed numerous articles on his travels to periodical literature, and published a small volume entitled "Voyage à la Sierra-Nevada de Sainte Marthe." Later he wrote two books dealing respectively with the earth and the ocean. He began at Clarens, on the Lake of Geneva, the work of his life—the "Nouvelle Géographie Universelle," the first volume of which appeared in 1876. The work was issued in parts, and was completed in 1894, the whole occupying nineteen volumes. On the conclusion of this great task Reclus began another work dealing with the historical side of human development, *i.e.* with history as influenced by geographical conditions. He left this book, it is said, in a complete state, ready for publication.

The death of Prof. Hermann Northnagel, of Vienna, in his sixty-fifth year, is announced. He made many contributions to medical literature, and by these and his discoveries in regard to heart action he was well known in the medical profession. Prof. Northnagel was a corresponding member of the Royal Medical Society of this country.

Many of our readers will be glad to learn that steps are being taken to raise a memorial to the late Prof. G. B. Howes, F.R.S. In the circular letter on the subject which has reached us it is pointed out that his death was probably due most of all to overstrain occasioned by his unsparing zeal in the acquisition of full and accurate knowledge and the undeviating readiness with which he imparted the fruits of his genius and learning, not only to his regular pupils, but to every association which asked for his assistance. It is proposed that the memorial shall take the form of an endowment fund for his widow and daughter. Subscriptions should be sent as soon as possible to the honorary treasurer, Mr. Frank Crisp, 17 Throgmorton Avenue, E.C., marked on the cover "Howes Memorial Fund." We trust there will be a generous response to the appeal.

A meeting of members of the Essex Field Club took place, by invitation of Lady Warwick, at Easton Lodge on Saturday last to inaugurate a photographic and pictorial survey and record of Essex. The object of the scheme is to make a permanent collection of photographs and other pictures of objects of interest, also maps, plans, and other documents, in order to give a comprehensive survey and record of all that is valuable and representative of Essex. The pictures, plans, &c., will be deposited and placed on view in the museum of the Essex Field Club at West Ham, and it is hoped that all the photographic societies and unattached photographers of the country will assist the committee in its work that its object may be attained.

We are indebted to a correspondent for a copy of a supplement to the Selangor *Government Gazette*, dated April 28, containing a report from the district surgeon of Klang on "the progress of anti-malarial measures carried out at Klang and Port Swettenham," in the Federated Malay States, during the past four years, from which we learn that in 1901 malaria was very prevalent both at Klang and Port Swettenham, there being much swampy ground in which, as well as in wells, ditches, and pools, Anopheles were found breeding. Active work was undertaken in the shape of tree felling, the clearing of undergrowth, the filling up of abandoned drains, the inauguration of a system of drains to carry off and prevent

the stagnation of rain water, the notification, and if necessary the removal to hospital, of cases of malaria, and the use of kerosene and the administration of quinine, with such marked success that at the present time malaria has practically, if not absolutely, disappeared from the places where the aforesaid measures have been carried out, while the remainder of the district remains much as it was. The report is a striking testimony to the value of the discovery by Major Ronald Ross.

A COMMITTEE appointed some years ago by the laboratory section of the American Public Health Association has recently issued its report on standard methods of water analysis. The committee in formulating the report has ascertained in a comprehensive manner the views of American analysts in regard to the bacteriological, chemical, physical, and microscopical examinations of water, and much cooperative work has been done in connection with the differentiation of species of bacteria. The need for greater uniformity in water analysis methods is universally recognised, and in the further standardisation of analytical and bacteriological methods in this country regard should be had to the report of the American committee. The part dealing with the identification of species of bacteria would appear to be specially valuable. The report is reprinted from the *Journal of Infectious Diseases* (May).

IN connection with the Agricultural Education and Forestry Exhibition at the recent show of the Royal Agricultural Society there was a section devoted to meteorology, organised by the Royal Meteorological Society. One feature was a typical climatological station with all the necessary instruments; another was an exhibition of diagrams, maps, photographs, &c., illustrating the effect of weather upon agriculture. Barometers, thermometers, rain gauges, sunshine recorders, &c., were also shown, and an address was given each day by Mr. W. Marriott on meteorology in relation to agriculture.

WE have received from the meteorological reporter to the Government of India (Dr. G. T. Walker) the *Monthly Weather Review* for November, 1904, and the *Annual Summary* for 1903. In the *Monthly Review* the data are presented from two different points of view:—(1) the prevalence and spread of diseases, and (2) their connection with agricultural questions. For this purpose India has been divided into two large groups of divisions, from what may be termed the medical and agricultural standpoints. The vastness of the area, and the number of tables that the discussions necessitate, are somewhat bewildering. The *Annual Summary*, however, completes the discussion, and the aggregate data are presented in an elaborate but clear and able manner. From the agricultural standpoint, India is divided into 57 meteorological districts; the tables show, for each element, the departures of the monthly and annual mean values for 1903 from the averages of past years, and the leading features are clearly illustrated by a series of carefully prepared charts.

THE English titles of the *Journal of the Meteorological Society of Japan* for May show that it contains several interesting articles, *e.g.* on the earthquake of April 15, the hot wind at Taito in Formosa, and others. Mr. T. Okada contributes a note in English on the relation between the pulse-rate and atmospheric pressure. The author quotes a table by Prof. Clayton, who made an ascent of Pike's Peak in 1901 by means of the railway, and therefore without exertion, and Mr. Okada has calculated the atmospheric pressure at each station up to 4313 metres, from Hann's simplified barometric formula. A glance at the table shows that the pulse-rate regularly increases with decrease of atmospheric pressure, and he gives a simple equation by the use of which the actual and calculated values exactly agree. This formula shows that a decrease of 9 mm. of pressure causes an increase of one beat of the heart per minute.

WE have received a copy of the report and results of observations for the year 1904 at the Fernley Observatory, Southport. The work carried on at this institution is of considerable importance; the observatory represents the coast district of the north-west of England, between Liverpool and Fleetwood, while somewhat to the east is the inland observatory of Stonyhurst. All these stations, except, perhaps, Fleetwood, are equipped with complete self-recording instruments. The Southport Observatory undertakes, in addition to the usual work of a first order station, considerable experimental work connected with rainfall, evaporation, wind, &c., at various subordinate stations in its vicinity. It also publishes a useful table of comparative climatological statistics at health resorts and large towns. The tables show that at Southport the year 1904 was very dry, the rainfall being 7·4 inches below the average. The maximum shade temperature was 82°·4, on July 11, and the minimum 22°·0, on November 27; the lowest radiation temperature was 13°·4, on February 29. The director is Mr. J. Baxendell, meteorologist to the Southport Corporation, and the chief assistant Mr. F. L. Halliwell, who, in connection with Mr. Baxendell and Mr. W. H. Dines, has invented several large sensitive recording instruments which are now adopted at various important stations.

THE Board of Agriculture and Fisheries has received, through the Foreign Office, a copy of a despatch from the British Consul at Munich reporting that 200,000 eggs of a new kind of whitefish (*Coregonus Albula*) of the Salmonidæ family, imported from Lake Peipus, in Russia, were hatched last year with excellent results at the fish-breeding station at Starnberg, near Munich. It is the intention of the Bavarian Fisheries Society, under which the experiments have taken place, to continue trials for five consecutive years to the same extent as hitherto, in the hope that the fish first placed in the different lakes may have spawned by then.

THE *Bulletin of the Johns Hopkins Hospital* for May (xvi., No. 170) contains papers on various medical subjects and on cancer, &c., in bitches. Dr. Hemmeter, in an article of considerable interest, discusses the history of the discovery of the circulation of the blood. He remarks that no less than six individuals have been credited with this discovery—Servetus by the Spaniards, Colombus, Ruini, and Cesalpinus by the Italians, Harvey by the English, and Rabelais by the French. He then proceeds critically to survey the evidence for and against the claims of these, and also of Galen, Malpighi, and others whose anatomical discoveries were almost necessarily precursors of the conception of the blood circulation. Dr. Hemmeter finally concludes that "the discovery of the circulation of the blood was the work of almost a millennium from Aristotle and Galen to Harvey, but the one who first logically drew true consequences out of hundreds of years of preceding work, and upon whose broad intellectual shoulders all subsequent investigations rested, was William Harvey; and to-day, 328 years after his birth, we may side without reservation with the words of Bartholin: "At Harveyo omnes applaudunt circulationis auctori."

ANOTHER mounted specimen of the great auk has just been sold to a Continental museum by Messrs. Rowland Ward for 400*l*. There are, it is said, practically seventy known specimens, most of which are in State museums.

EXPERIMENTAL work for the purpose of protecting the sugar-growing industry in the Sandwich Islands has been undertaken by the new owners of the group with characteristic energy, and we have before us the first issue of Entomological Bulletins published at Honolulu on behalf of the Experiment Station of the Hawaiian Sugar Planters' Association. The present part is the first instalment of a series to be devoted to the homopterous insects commonly known as leaf-heppers (jumping relatives of the ordinary aphides, or plant lice) and their enemies, and treats of the minute parasites known as Dryinidæ, by which these pests are themselves attacked. Attempts have been made to introduce foreign dryinids into Hawaii in order that they should assist in keeping down the leaf-heppers, but at present with only partial success, owing to the fact that some of the introduced kinds do not prey on these insects. Any leaf-hepper attacked by a dryinid may be reckoned as good as dead, for even the contents of its head and eyes are mercilessly sucked dry by its uninvited "guest." The truth of the old rhyme about "little fleas and lesser fleas" is, however, forcibly emphasised in the case of these parasites, which are in turn attacked by what our American friends are pleased to call hyperparasites. "How hardly the dryinid parasites," writes Mr. R. C. L. Perkins, the author of the paper and director of the experiment station, "are at times pressed by their various hyperparasites, we often observed. To cite one instance, from about fifty cocoons of several species of parasites obtained near Cairns, one solitary male alone emerged, all the rest being hyperparasitised, and similar observations were made in several localities."

DR. WILLIS's annual report of the Royal Botanic Gardens, Peradeniya, Ceylon, for 1904 is chiefly devoted to the work connected with investigations in economic botany. As a new departure, the formation of a cotton experiment station in the dry region of north-central Ceylon, supplied with water from irrigation tanks, is of primary importance. The difficulty of clearing the land was enhanced by scarcity of coolie labour, but the soil is excellent, and the situation seems to be well suited to the production of Sea Island cotton; rubber is also being experimentally cultivated in this region. In connection with rubber, the checking of the canker disease observed on two Hevea plantations and the high values obtained for some samples of Castilloa rubber are of interest.

MR. E. P. STEBBING contributes a note to the *Indian Forester* (May) on the satisfactory results which have been obtained by soaking bamboos in crude Burma petroleum in order to keep off the boring beetles, species of Dinoderus known as shot-borers. The article by Mr. G. H. Myers, a member of the Bureau of Forestry, on "Forestry Education in the United States," is noteworthy as indicating the aspirations which stimulate this and similar departments. The importance of practical training and of a knowledge of American requirements is emphasised.

AN hereditary abnormality in the human hand and foot and its relation to Mendelism form the subject of an article published in the papers of the Peabody Museum of American Archæology and Ethnology (vol. iii., No. 3). The abnormality in question came under the notice of the author, Dr. W. C. Farabee, some years ago in Pennsylvania, and consists in the suppression of one phalange, or joint, in each of the fingers and toes, with the exception of the thumb and great toe, which were abnormally shortened. The whole hand was extremely short and "podgy," and this feature was associated with shortness of bodily stature. Thirty-seven persons, all related, were affected with the malformation, which was inherited in accordance with Mendel's law for five generations. Although a tradition that every other child in the family had short fingers did not prove to be exactly true, yet almost precisely half the number of offspring displayed the abnormality. In one instance a regular alternation of normal and abnormal individuals continued until the eighth child. The total number of offspring descended from the original abnormal individuals is 69, of whom 33 are normal and 36 abnormal, distributed as follows:—in second generation, 4 normals and 4 abnormals; in third, 5 and 7; in fourth, 7 and 9; and in fifth, 17 and 16. The case affords strong confirmation of the general truth of the Mendelian doctrine.

THE general report of the Geological Survey of India drawn up by the director, Mr. T. H. Holland, F.R.S., shows that during the past year much valuable work has been done, and that results of scientific interest as well as of immediate economic importance have been obtained. Among advances of unusual scientific interest is the discovery of a new series of the remarkable family of elæolite-syenites near Kishengarh, in Rajputana. In economic work the department has kept in touch with the numerous developments of private enterprise in the mining of coal, gold, manganese ore and salt, and has demonstrated the existence of iron ores of industrial value. An interesting discovery is that India possesses a possibly valuable asset in the deposits of laterite, which cover considerable areas in the peninsula and in Burma, as it is shown that laterite often exhibits the essential characters of bauxite. The subject is dealt with exhaustively in the *Records of the Geological Survey of India* (vol. xxxii., part ii.) by Mr. Holland, who gives analyses of the best samples which have so far been tested. These laterites or bauxites were collected in the Madras Presidency, in the Central Provinces, in Central India, in Bengal, and in Bombay, and the percentages of alumina reach as high as 67·88. In the same issue of the Records Mr. Holland publishes returns of the Indian imports and exports of mineral products in 1904. The export of 154,880 tons of manganese ore is a remarkable feature, and the rapid increase in the export of Indian mineral oil is also noteworthy.

WE have received from the Peruvian Government copies of Bulletins Nos. 22 and 23 issued by the Corps of Mining Engineers. The former is a monograph on the mineral resources of the province of Otuzco, by Mr. F. Malaga Santolaya. The province contains rich deposits of gold and silver ores and coal of good quality, as well as ores of copper, lead, manganese, and antimony. The second bulletin is a report of a commission on the Cerro de Pasco mines, signed by the chairman, Mr. C. E. Velarde. It contains a useful summary of the Peruvian mining law and a detailed description of the Cerro de Pasco deposit, originally worked as a silver mine, but now with increasing depth yielding chiefly copper ore.

THE Sociological Society has issued a pamphlet containing an address by Dr. James Bryce on the aims and programme of the society, together with the first annual report of the council and a list of members. The report outlines the circumstances attending the inauguration of the society, and enumerates the aims which it has in view. A brief account of each of the meetings held during the

year with which the report is concerned is given, and a statement of accounts supplied. Dr. Bryce points out in his address that the members of the society may be divided into three classes, viz. those who devote themselves specially and scientifically to the business of research in all those lines of inquiry which concern man as a social being; those interested in sociology as educated and intelligent men; and practical men who are not able to devote themselves entirely to scientific study, but have to deal with sociological problems in the course of their daily life.

THE first number of a new periodical devoted to birds has just made its appearance at Cape Town. It is called the *Journal of the South African Ornithologists' Union*, and is the organ of the association recently formed under that name. Besides information relative to the new union and reports upon the proceedings of its first meetings, this number contains original articles upon South African birds by Major Sparrow, Mr. F. J. Ellemor, Mr. G. C. Shortridge, and Mr. A. Roberts. The journal is edited by Mr. W. L. Sclater (the president of the union), Dr. Gunning, and Mr. Bucknill, and will appear at irregular intervals, "when sufficient matter has been received."

MANY inquiries having been made for part ii. of the *Museum Boltenianum*, 1798 (which relates to Mollusca, and is very scarce), it has been decided to reproduce a few copies by photographic fascimile from the Crosse copy now in the British Museum (Natural History), and to sell the same at 2*l*. per copy if a sufficient number of subscribers be forthcoming. The work, if issued, will be produced under the supervision of Mr. F. W. Reader. Those wishing to subscribe should apply to Mr. E. R. Sykes, 3 Gray's Inn Place, Gray's Inn, London.

THE *Journal of the Royal Sanitary Institute* (vol. xxvi., No. 6) is mainly devoted to housing problems. Mr. Turton introduces a discussion on re-housing tenants dispossessed from insanitary property, Dr. Louis Parkes a second on housing in mansions let as flats, and Dr. Robertson a third on certain aspects of the housing problem.

THE *Psychological Bulletin* (vol. ii., No. 6) contains a report of the proceedings of the north central section of the American Psychological Association, a paper by Raymond Dodge on the illusion of clear vision during eye movements, various reviews, notes, &c.

A SECOND edition of the "Key to the Classifications of the Patent Specifications of France, Germany, Austria, Norway, Denmark, Sweden, and Switzerland in the Library of the Patent Office" has now been published at the Patent Office. The price of the "Key" is 6*d*.

MR. JOHN MURRAY has just issued the ninth edition of Mr. Edward Whymper's guide to "The Valley of Zermatt and the Matterhorn," and the tenth edition of his guide to "Chamonix and the Range of Mont Blanc." The price of each volume is three shillings net.

WE have received from Messrs. Hurst and Blackett a copy of a map of Lhasa drawn to a scale of 4 inches to a mile. The map is based on the survey in 1904 of Captain C. H. D. Ryder and Captain H. M. Cowie, with a few additions by Mr. Perceval Landon.

THE first of a series of illustrated papers by F. J. Sprague on "The Electric Railway" appears in the *Century Magazine* for July; it gives many interesting particulars of the early experiments made in electric traction.

THE articles contained in the *Bulletin of the Johns Hopkins Hospital* for June (vol. xvi., No. 171) are all of considerable medical interest, and comprise papers on the ætiology and pathogenesis of pernicious anæmia, by Dr. Bunting, on recurrent phlebitis, by Dr. Briggs, on heart block in mammals, by Dr. Erlanger, &c.

MESSRS. GURNEY AND JACKSON announce the preparation in three volumes of a translation by Dr. C. A. Keane of Lunge's "Technical Methods of Chemical Analysis."

WE are asked to state that Mr. C. S. Sargent's "Manual of the Trees of North America (exclusive of Mexico)," which was reviewed in our issue for June 29 (see p. 197), is published in England by Messrs. Archibald Constable and Co., Ltd., 16 James Street, Haymarket, and that its price is 25*s*. net.

OUR ASTRONOMICAL COLUMN.

JULY AND AUGUST METEORS.—We have now nearly arrived at what is the most interesting period of the year for the meteoric observer. With skies often clear, with the air at an agreeable temperature, and with meteors visible in more than usual abundance, success is promisingly offered to everyone who practically enters upon the study of this important and complicated branch of astronomy.

In the previous months of May and June, with their strong twilight and a scarcity of meteors, there has been no special inducement to observers, but after the third week in July the nights will become perceptibly darker, early Perseids will begin to manifest themselves, and many Aquarids will probably appear towards the close of the month from a radiant at 339°–10°. Active showers in Sagittarius, Pegasus, Draco, Cygnus, Cepheus, Andromeda, and Cassiopeia will also be observed, but the radiant points will be more remarkable for their variety and number than for striking activity in individual cases.

It is an interesting feature in observations at this time of the year to watch the Perseids from their earliest arrivals (about July 15) to their most belated apparitions (about August 21), and to trace the motion of the radiant point towards the E.N.E. In the following table the position of the radiant is given for every third night:—

Date	Radiant α δ	Date	Radiant α δ
July 18	18°·0+50°·1	Aug. 5	37°6+55°·7
,, 21	20·8+51·1	,, 8	41·5+56·5
,, 24	23·8+52·2	,, 11	45·7+57·1
,, 27	27·1+53·2	,, 14	50·0+57·7
,, 30	30·5+54·1	,, 17	54·4+58·2
Aug. 2	33·9+55·0	,, 20	58·9+58·7

Moonlight will not much interfere with observation during the period from July 25 to August 9. At the time of the Perseid maximum (either on the morning of August 12 or 13) the moon will set as follows:—

	h. m.
Thursday, August 10	12 52
Friday, August 11	13 45
Saturday, August 12	14 45

The moon will be increasingly gibbous, and though many meteors will doubtless be exhibited before moonset, it will be very advisable to count the number visible in the dark sky after our satellite has gone down, and particularly on the last two dates mentioned above, as the maximum is likely to occur between 2h. and 3h. 30m. a.m. when the radiant is high.

To give anything like a comprehensive list of the radiant points visible in July and August would require a large space, and is, moreover, unnecessary, a pretty complete summary of them having been published in *Astronomische Nachrichten*, No. 3874, for 1903 June 3.

THE FORMATION OF THE MARTIAN SNOW-CAPS.—A short note communicated by Prof. W. H. Pickering to No. 6, vol. xiii., of *Popular Astronomy* states that on examin-

ing a number of photographs of Mars, which were secured with the 11-inch Draper telescope during the period March 31 to April 30, it was seen that no snow-caps properly so-called appeared until April 23. The photograph of March 31 showed clouds on both the terminator and the limb, but no polar caps. On April 23 a clearly visible and extensive light area appeared at the southern pole, but was not bright enough for snow, rather resembling an extensive region of clouds. A very small light area appeared near to the northern pole on April 15, but was only seen with difficulty. A visual examination with a 24-inch reflector revealed the southern polar cap on April 30 as extending far towards the north in long. 340°.

Prof. Pickering thinks that when the clouds disperse snow will probably be revealed lying in their place. He also contends that the observed seasonal colour-changes from brown to green on such features as the Mare Erythræum is the surest evidence of the existence of vegetation on Mars.

RECENT OBSERVATION OF EROS.—From an equatorial observation of Eros on June 12, in which the planet's position was referred to that of δ Capricorni, Prof. Millosevich determined the following position:—

(1905 June 12d. 14h. 32m. 24s. M.T. Rome).
α (app.) = 21h. 48m. 41·74s. δ (app.) = −16° 41′ 35″·3
(*Astronomische Nachrichten*, No. 4029.)

STANDARD TIME IN VARIOUS COUNTRIES.—An interesting and useful summary of the present status of the use of standard time the world over is given in appendix iv., vol. iv., of the *Publications of the U.S. Naval Observatory*. The director of the observatory, Rear-Admiral Chester, has prepared various tables in which he shows the relation of the standard time employed in each country, state, or colony, to the meridians of Greenwich and Washington. In the first table is given a summary of nations that use standard time, and it shows that, of the thirty-six nations specifically mentioned, twenty employ Greenwich time as the basis of their systems. The areas and population concerned in these twenty nations form a very large majority of the totals, and of the remaining sixteen no two agree. This Mr. Chester regards as a powerful argument in favour of the adoption of a universal time system.

Other tables show in detail the present status of the time systems employed in a large number of localities, and enumerate the dividing lines separating those contiguous areas in which different standards are in use.

HARVARD COLLEGE OBSERVATORY ANNUAL REPORT.—In the forty-ninth annual report of the Harvard College Observatory Prof. E. C. Pickering, dealing with the year ending September 30, 1904, gives a brief outline of the progress made in each of the many and various researches which are being carried out at that observatory.

Variable stars and asteroids were photometrically observed, with the polarising photometer, by Prof. Wendell, who, *inter alia*, found that the asteroid [7] Iris varies about one-quarter of a magnitude in a period of 6h. 12m. The measurement of all the Durchmusterung stars in zones 10′ wide at intervals of 5° was continued with the 12-inch meridian photometer, and the observations of many of the zones are now practically complete.

543 photographs taken with the 11-inch Draper telescope brought the total number secured with this instrument up to 15,030, and 1116 photographs were secured with the 8-inch Draper telescope, raising the total up to date to 32,094. It is proposed to extend this work to the spectra of the fainter stars by giving exposures of sixty minutes' duration and using only one prism. Many objects having peculiar spectra were discovered by Mrs. Fleming during the examination of the Draper photographs.

The Boyden and Bruce telescopes were employed continuously, and from the examination of the long-exposure chart plates Prof. Frost discovered many new nebulæ, &c., including 203 nebulæ in Virgo where the Dreyer (N.G.C.) catalogue mentions only 58.

The meteorological observations were continued at the Blue Hill Observatory, kites being employed on fourteen occasions. The average maximum height reached by the kites was 7750 feet above sea level, the maximum altitude attained on one occasion being 14,660 feet.

THE ACADEMIC SIDE OF TECHNICAL TRAINING.[1]

IT is not so very long ago that engineers, at any rate, became willing to recognise that technical training had an academic side at all. Almost the first, and still undoubtedly the greatest, representative of the academic side of our profession was the late W. J. Macquorn Rankine, who, after eighteen years of practical engineering experience, became professor of engineering in Glasgow in 1855, and held the chair until his death in 1872, and some of whose pupils have occupied, and now occupy, very high positions in the profession for which he did so much. Perhaps it may be said that Rankine was by nature rather a physicist dealing with engineering problems than an engineer (in spite of his love for the "three-foot rule"[2]) dealing with engineering problems. But only those of us who have had occasion carefully to study his work from the point of view of trying to teach subjects similar to his can ever know what an extraordinary physicist he was. But up to the years 1870 and 1880, Rankine's pupils and their contemporaries were not yet old enough to influence the body of the engineering profession, and there still existed a pronounced dislike on the part of an enormous number of engineers to anything academic, a dislike which can hardly be realised now by those who see the various professional bodies vieing with one another in their endeavours to ensure that their members shall have a proper and complete scientific training.

Now all the great engineering societies have recognised formally that no engineering training is complete without its academic side, and a very important committee, consisting of delegates from the five great engineering societies, with Sir William White as president, has been at work for some time, formulating their ideas as to the nature of the qualifying training, and going so far as to formulate also ideas as to the preliminary education of young engineers before they commence their academic training. I do not wish—rather I do wish very much, but it is not my subject to-day—to enter upon the very thorny questions involved in what that preliminary education ought to be according to the notions of a grown-up engineer. I will say, however, for it is no secret, that communications received from many headmasters of our great schools, while not going so far as some of us would like, are yet quite astonishingly radical in their ideas as compared not only with thirty, but even with fifteen years ago.

As to the general trend of our academic training, I think we engineers are entitled to say that it should be so arranged as best to train the best engineers. I put it in this way because I mean it to be understood that while on the one hand the *best* engineer is certainly not the man who knows his own business only and narrowly; on the other hand, I think we are entitled to demand that the engineer should not be looked upon as the mere bye-product of the training, but as the chief result to which other things are to be subordinated. I think that University College is not likely to fall into this mistake, but the point has really to be kept in mind in cases where, as here, the engineering education is only one branch of the wide range of education covered by the whole work of a university college.

In saying this, however, I particularly do *not* mean that the academic training of engineers should be laid out exactly on superficially utilitarian lines. The idea of giving a young man just as much mathematics, just as much physics, or just as much chemistry as the minimum that he can professionally require, is not only pernicious, but absolutely fallacious. I am sure that the only way of knowing a subject up to a certain point in such a fashion that, up to that point, it can be thoroughly utilised, is to study the subject up to a point very much further advanced. It is not at all a valid objection to the teaching of any particular point in mathematics or physics that it is more

1 Abridged from an Address delivered before the Union Society of University College, London, on June 29, by Dr. Alex. B. W. Kennedy, F.R.S.

2 Some talk of millimètres, and some of kilogrammes,
And some of décilitres, to measure beer and drams;
But I'm a British workman, too old to go to school;
So by pounds I'll eat, and by quarts I'll drink, and I'll work by my three-foot rule."

complicated or more advanced than anything which the engineer will be likely to require. That, in itself, is not an objection at all, because, as I have said, it is impossible really to master a scientific subject up to a certain, often very elementary, point without having at least a superficial knowledge of a much greater extent of the subject. But it is desirable, indeed necessary from our point of view, that the advanced work in purely scientific subjects should be specially chosen so as best to deepen and make certain the knowledge of the earlier work. This may be, and almost certainly is, a very different thing from choosing it so as to form the best basis for still further study of the particular science in question. In this connection I must point out—at least as my opinion—that it is a mistake to consider that there is only one mathematics or one physics, and that either the preparatory work or the whole teaching must necessarily be the same for everybody—for the man who is to devote himself to engineering, or for the man who intends to spend his life in physical work. For instance, I think an engineering student may be allowed to take for granted that A times B is equal to B times A (he is always quite prepared to believe it), and that it is perfectly reasonable to make to him dogmatic and probably in a sense erroneous, statements as to atoms (let us say) or as to the ether, without any of the qualifications which would be necessary supposing the atoms and the ether were to form the basis of the man's future studies.

It is no doubt a noble conscientiousness which sometimes prevents a man who is in the front rank among men of science from making to his students, as quite general, statements which he knows to be true only with qualifications or limitations. But the case is one in which often the general statement, given with authority, will really give the student a truer conception of the facts than a more accurate statement which is guarded by reasoning and explanations which he (that is, the student) cannot understand, and will almost certainly misunderstand. As a writer in NATURE put it a few days ago, referring to the theory of quaternions, "the truth is that very few students are able to appreciate to the full an absolutely logical argument until they have a certain amount of practical knowledge imparted to them more or less *by authority*."

There is one matter in connection with the teaching both of mathematics and physics to engineering students which I think might well be emphasised more than is generally the case. Whether it is desirable that it should be emphasised in dealing with the general student I do not venture to say. I mean the point that the answer to any question can only be as accurate as the data of that question. For the ordinary examination question in mathematical physics it is necessary and unavoidable to presuppose certain data which in real life are absurd and impossible. In the ordinary everyday questions of engineering there is nothing more misleading than to take for granted the data of the examination paper, and a very great deal of the disrepute into which mathematical work had fallen at one time among engineers was due to the fact that although the average student was able to use his methods rightly, he was unable to perceive whether they led him to a right result. I think it must be possible, even if it is not exactly easy, to point out to the student the extent to which the accuracy of his answers is influenced by the assumptions which he makes.

It is, I am afraid, too often presumed that the method of working out the answer is the chief thing; perhaps it may be from some particular point of view. But for our purposes, foolish as it may sound, the method of working out the answer is only secondary; the answer itself is the chief thing, and we really must have that answer right when it finds itself translated into steel or stone. We would much sooner have a right answer got by an imperfect method than a wrong answer got by the best method in the world. And an answer may be wrong in two ways; it may be wrong because the data are in themselves wrong, that is to say, inapplicable to the particular case, or it may be wrong by being stated in a form much more accurate than the real data will allow of, as when we find the indicated horse-power of engines given to six significant figures, when we know perfectly well that the fourth must always be doubtful.

It would be most useful if our scientific professors would discuss these points with their students and show them specially the extent to which the methods and theorems of the mathematician and the physicist may be properly applied when the only data available for the problems are such as actually are found in practice. It is hardly fair to leave the engineering professor to tell his pupils, or to leave the engineer to tell his assistants, that the methods they are using are quite inapplicable, and the results which they are getting obviously inaccurate. This is in every way inadvisable, and may lead the otherwise guileless student to discount all his teachers instead of only one. Every scientific experimenter knows that it is often the most difficult part of his work to say how alterations in data or want of knowledge of accuracy in data may affect the result, and I should like much to see this matter systematically dealt with by the teachers who have actually to do with the scientific or theoretical treatment of the questions concerned. If they have any doubt as to what is the general nature of the complex engineering questions which have to be solved, a letter addressed to any engineer in Westminster would bring them the fullest information. But happily most of the university colleges now have engineers on their Senates, so that the information can be had without going outside their own walls.

As to the more advanced part of engineering teaching in colleges, I want to put forward an idea that I have more than once had occasion to express. I should much like to see the development of some such connection between old and distinguished students of a college, who become later on older and more distinguished engineers, and the college at which they have studied or some other college, as exists in the similar case of the medical profession. My suggestion is that to get the full benefit from its best pupils, a college should, if possible, keep in touch with them after they have left it. A few years after they have left college, and when they have fairly got into the swim of professional work, but before they have so much lost touch with the difficulties of their college days that they no longer appreciate the student's point of view, they might be made to help in teaching by giving lectures on the special branches of engineering with which they were specially and actively familiar. They should do it before they have forgotten what they formerly learnt, or have had it driven out of their heads by the pressure of other ideas, and while college methods and points of view are still familiar. They would be men still making their way in their profession, still, let us hope, full of enthusiasm for their work, and certainly they would be daily finding out the differences between actual and academic problems. Teaching of this kind could in no way replace the general preliminary teaching of engineering subjects in the college, which must continue to be given, as it is given now, by a professor or professors, the bulk of whose time is spent at the college, and who are thoroughly in touch with all the students.

I confess that I hope a time will come when in any case professors of engineering will not remain permanently in academic harness, but will come out and take their place—a most important one—as colleagues among the active and leading engineers of the country, and will look upon such a position as that which they ought to reach rather than a solely academic position, however eminent. But, in addition to the work of the permanent professor or professors, I believe that old students coming back in the fashion I have indicated, not in one only, but in several branches of engineering, and giving short courses of special lectures to third year students, would very much help both the students and the rest of the teaching staff. The arrangement would also have the very great advantage of bringing about a closer and warmer connection between the men who are at work in their profession and the colleges where they were trained. It would also help to keep the colleges themselves in that actual and continual touch with engineering things and ideas which is so absolutely essential for their continued usefulness.

It will be noticed that the scheme I have outlined is closely analogous to the system already general in connection with medical training, where the lecturing and professorial staff on the technical side consists almost entirely of old students (occasionally from other colleges) who are beginning to make their way professionally, or who, by the time they have become professors, have actually made their way to the highest ranks of their profession.

HARVEY AND THE PROGRESS OF MEDICAL SCIENCE.[1]

AFTER some introductory remarks, Dr. Roberts referred to Harvey's work, and especially to his great discovery of what is commonly spoken of as the "circulation of the blood," though his published treatise is really on the "movements of the heart and of the blood." He re-affirmed their implicit belief in the absolute priority of Harvey's claim to this discovery, and spoke of its magnitude and far-reaching effects, which had been described in various and glowing terms, in no way exaggerated. Nor must they forget the formidable difficulties under which Harvey carried out his investigations; the profound errors which he had to combat and overthrow, and the confusion he had to clear away; his indomitable perseverance; and the masterly yet courteous manner in which he disputed and ultimately overcame the objections which had been raised against his views.

The orator then gave an outline of Harvey's career, dealing more especially with his association with the College of Physicians, where he held the position of Lumleian Lecturer from 1615 to 1656, in the very first course of lectures presenting a detailed exposition of his views concerning the circulation of the blood, which continued to form one of his subjects for several years. In the deed by which Harvey conveyed to the college his estate, he laid down three definite and distinct injunctions or instructions as to the subject-matter of the oration, which it was their duty to follow. The first injunction is that "there shall be a commemoration of all the benefactors of the said College by name and what in particular they have done for the benefit of the said College, with an exhortation to others to imitate these benefactors and to contribute their endeavours for the advancement of the society according to the example of those benefactors."

Dealing with this injunction, Dr. Roberts first mentioned individually Harvey himself; Thomas Linacre, the practical founder of the College of Physicians; and John Caius. He then considered generally as benefactors those who had held high office, alluding specially to that of President; those who had founded lectureships, or had given endowments for prizes, medals, or scholarships; those who had contributed to the library or to the general funds; and those who by their professional or scientific attainments and achievements, as well as by their high personal character, general culture and scholarship, and intellectual and moral qualities have shed unfading renown and lustre upon the College of Physicians.

In discussing the second injunction, namely, to "exhort the Fellows and Members of this College to search and study out the secrets of nature by way of experiment," the orator made a passing allusion in favour of vivisection, claiming for this method of investigation the cordial support of the medical faculty as a whole, with comparatively few exceptions. After referring to what the College had done as a body in advancing scientific research, he enlarged upon the great activity and promising aspects of modern research, more particularly in relation to subjects connected with the medical profession, and expressed his belief that Harvey would be amazed and fully satisfied were he to come on the scene at the present time, and realise the extent and thoroughness with which his exhortation is being carried into effect in all directions. Dr. Roberts then gave an abstract of what he had prepared for the oration with reference to the progress of knowledge and practice in connection with the circulatory system since Harvey's time, and the methods by which it had been brought about. He also directed attention to some of the more prominent examples of the beneficial results on an extensive scale of scientific and practical research, and alluded specially, as being closely connected with the circulatory system, to the "brilliant victories" which had been achieved against malaria in various parts of the world, many of them forming an integral part of this vast Empire. While paying a tribute of respect and admiration to all those who at the risk of life and health have gone forth to dangerous climates to study and fight against this and other tropical diseases, Dr. Roberts mentioned specially Dr. J. E. Dutton, the latest "martyr of science," as he had been aptly called, whose lamented death recently occurred on the Congo, where he had gone to study sleeping sickness on behalf of the Liverpool School of Tropical Medicine. He expressed on behalf of the college their deep sense of the great services which Dr. Dutton had rendered to the medical profession and to humanity, their profound regret at the premature cutting off of such a valuable life and promising career, and their heartfelt sympathy with his bereaved family and friends.

The orator concluded as follows:—The last and most agreeable duty laid upon me by Harvey's direction is to "exhort the Fellows and Members, for the honour of the profession, to continue in mutual love and affection among themselves, without which neither the dignity of the College can be maintained, nor yet particular men receive that benefit by their admission into the College which they might expect, ever remembering that *concordia res parvae crescunt, discordia magnae dilabuntur.*" With regard to the future position and reputation of this college in relation to scientific research and the progress of medicine, there can be no doubt or misgiving when we see amongst our younger fellows and members so many who are endowed with great abilities, who are full of energy, intellectual vigour, and enthusiasm in their work, and whose achievements have already brought them into conspicuous prominence and, in some cases, into the foremost ranks of our profession. May we not confidently hope that they will also ever keep in mind Harvey's last exhortation, and unflinchingly strive to maintain the high standard of character and conduct which he has placed before them? But should they at any time feel the need of an example, a stimulus, or an inspiration, let them steadily fix their attention and thoughts upon the personality, the life, and the work of our "immortal and beloved Harvey," whom it is our privilege and pride and happiness to commemorate on this anniversary.

[1] Abstract of the Harveian Oration delivered at the Royal College of Physicians on June 21 by Dr. Frederick T. Roberts.

HIGH TEMPERATURE RESEARCH ON THE FELSPARS.

AN elaborate investigation of the melting points of the felspars, devised and carried out by Messrs. Day and Allen in the physical laboratory of the United States Geological Survey, is described in a memoir just received.[1] The geological importance of laboratory research at high temperatures was strongly urged by the late Clarence King and Dr. Becker, and the well known work of Dr. Carl Barus has already furnished petrologists with a number of valuable data. The laboratory, discontinued in 1892 for want of funds, has been re-established by the exertions of Dr. Becker, and the piece of work before us has been in part subsidised by the trustees of the Carnegie Institution.

The authors describe in detail, for the benefit of other experimenters, the thermoelectric method by which they have been enabled to measure high temperatures with an error of not more than one degree. It was also found necessary to adopt some method of determining the instant of melting (where such exists) independently of the personal judgment of the operator. It appears that in

[1] "The Isomorphism and Thermal Properties of the Felspars." Part i. Thermal Study. By Arthur L. Day and E. T. Allen. Part ii. Optical Study. By J. P. Iddings. With an introduction by George F. Becker. Pp. 95; xxvi plates. (Washington, 1905.)

such minerals as the felspars the viscosity of the fused substance may be of the same order as the rigidity of the solid crystal approaching fusion, so that there is to the eye no abrupt change. The discordance between the results of different experimenters is largely attributable to this fact. The method followed was therefore to plot as a curve the relation between temperature and time, and to note the place where a change in the shape of the curve indicates an absorption of latent heat. To avoid the disturbing influence of impurities, the several felspars to be examined were prepared artificially. Thin slices of the crystallised products were studied optically by Prof. Iddings, and they are illustrated in the memoir by a series of beautiful plates.

FIG. 1.—Tabular Crystals of Bytownite from Middle of Crucible. From "The Isomorphism and Thermal Properties of the Felspars."

Anorthite was the felspar most easily crystallised, and its curve gave a sufficiently sharp melting point at 1532°. Other varieties examined had the compositions Ab_1An_5, Ab_1An_2, Ab_1An_1, Ab_2An_1, Ab_3An_1. These gave progressively lower melting points; but it was found that, in passing from anorthite towards the albite end of the series, viscosity rapidly increases and obscures the phenomenon of fusion, the break in the curve of heating becoming for Ab_3An_1 a barely perceptible deviation. For albite, and also for orthoclase, the method fails to give any result, and in a certain sense it may be said that the alkali-felspars have no melting point. In this connection, a special series of experiments gave some remarkable results. A small fragment of crystalline albite, embedded in albite glass, was heated to 1200° and slowly cooled. Thin slices showed that the crystal had melted to a glass only along cleavage and other cracks. The experiment was repeated with higher temperatures of heating up to 1250°, and it was found that, though the lanes of glass encroached more and more upon the crystal, considerable relics of the latter were still left, preserving undisturbed their original orientation. It thus appears that a mineral like albite, which melts to an ultra-viscous liquid, may be maintained for half an hour at a temperature well above its normal melting point without being completely fused. It seems doubtful whether the crystalline substance at such a temperature is to be regarded as a superheated solid or as a liquid crystal, in which deorientation is prevented by extreme viscosity.

Felspar		Melting Temperature		Specific Gravity: Crystals		Glass
Anorthite	...	1532°	...	2·765	...	2·700
Ab_1An_5	..	1500°	...	2·733	...	2·648
Ab_1An_2	...	1463°	...	2·710	...	2·591
Ab_1An_1	...	1419°	...	2·679	...	2·533
Ab_2An_1	...	1367°	...	2 660	...	2·483
Ab_3An_1	...	1340°	...	2·649	...	2·458
Albite	...	—	...	2·605	...	2·382

We reproduce in tabular form the chief numerical results obtained. The general conclusions arrived at are of great importance. The melting point curve for the lime-soda-felspars, as well as the curve of specific volume, is continuous, and not very different from a straight line, and we have almost conclusive proof that this group of minerals forms a truly isomorphous series. Further, it belongs to type i. of Bakhuis Roozeboom, the melting point falling steadily from one end of the series to the other. Here a further point of interest arises. According to theory, the crystals first formed from the fused mass should be richer in anorthite than the liquid from which they separate, and should contain an increasing proportion of albite as crystallisation proceeds. Day and Allen, however, verified in several cases that their crystals had the same composition as the mother liquid. This can only be due to undercooling, the beginning of crystallisation being deferred until the temperature had fallen below the range proper to normal crystallisation. Those natural rocks in which the felspar crystals show a zoned structure (the outer zones richer in albite) must have crystallised without undercooling, and, indeed, their felspars must have been formed within a certain range of temperature, which can be more or less closely determined. In this and other petrological applications the work of the authors affords a valuable supplement to that of Vogt.

A. H.

PRIMITIVE RELIGIOUS ART.[1]

WE have on several occasions directed attention to works by American ethnologists dealing with investigations on the meanings of the designs and patterns of aboriginal decorative art. This fruitful and interesting field of inquiry is by no means exhausted, and two papers on the subject have recently been published by the American Museum of Natural History which merit the careful attention of students. Dr. Clark Wissler has made a valuable study of the decorative art of the Sioux Indians which is a model of clear and concise expression and of adequate illustration. As he truly states, the investigation becomes psychological, because it is necessary to know what ideas the artists have of their designs, and what motives lead to their execution. The assumption that all primitive decorative designs are executed with consciousness that they symbolise some definite object or relation in nature is fairly supported by the facts so far accessible, but does it follow that these symbolic designs were produced by a gradual transition from the realistic representation? That some of them were so produced has been satisfactorily demonstrated; but is this the law of growth for decorative art? It appears, among the American Indians, that the more abstract the idea, the simpler and more geometric the design. On the other hand, it is obvious that a vigorous conventionalisation of representative forms must tend to reduce them all to a few simple geometric designs. In such an event, confusion as to the symbolic aspect of similar designs must arise in the minds of the artists, necessitating re-interpretation or creation of new symbols. Thus any given interpretation need have no certain relation to the origin of the design itself; indeed, the association of the symbol and the idea can be shown in some cases to be quite secondary. Amongst the Sioux there are two main kinds of decorative art—realistic painting and conventional bead- or quill-work; the former is done by the men and the latter by the women, and there is every reason for assuming that the pictographic mode is on the whole the older. One sex has often appropriated the designs used by the other to express divergent ideas, and thus we see how even within the same tribe two or more modes of expressing symbolic motives may make simultaneous use of the same graphic designs.

In a short paper of fifty pages on the decorative art of the Huichol Indians of Mexico, Dr. C. Lumholtz has managed to crowd some 350 figures, so that we have abundant material for study. All these designs, he says, are expressions of religious ideas that pervade the entire existence of these people; in other words, they are permanent prayers. Girdles and ribbons, inasmuch as they are considered as rain serpents, are in themselves prayers for rain and for the results of rain, namely, good crops, health, and life. All the designs on pouches, shirts, skirts, and so forth express prayers for some material benefit, or for protection against evil, or adoration of some deity. Thus the magic double water-gourd, even in its most conventionalised form, means a prayer for water, the source of all life and health. Animals like the puma, jaguar, eagle, &c., express prayers for protection, as well as adoration for the deity to which the creatures belong. The little white flower, *toto*, which grows in the wet, corn-producing season, is at once a symbol and a prayer for corn, and in all sorts of forms it is to be found woven in their costumes. Flowers play, and always have played, an important part in the religion of these Indians; with them flowers, like the plumes of birds, are prayers for rain and life. Dr. Lumholtz doubts if there is such a thing as ornamentation solely for decorative purposes among the Huichol, or, for that matter, among any primitive people. Prof. Boas points out that on the whole the style of decoration of ceremonial objects differs considerably from that of the ornamental parts of garments. The former are crude and pictographic, with slight tendency to conventionalism, while the latter are regular, well executed, and strongly conventionalised, and the general character of these designs much resembles that of similar designs found in other parts of Mexico and in Central and South America. These textile designs, which are of great variety and beauty, acquire much more interest from the suggestive interpretation of their symbolism which Dr. Lumholtz has afforded us.

The American Museum of Natural History is to be congratulated on possessing collections about which so much valuable information has been obtained, and students are to be congratulated on having these riches made accessible to them by means of such beautifully illustrated memoirs.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—An examination for a geographical scholarship will be held on October 12 next. Candidates, who must have taken honours in one of the final schools of the university, should send their names to the reader in geography, Old Ashmolean Museum, by, at latest, October 2. The value of the scholarship is 60*l.*

Dr. J. Ritchie, reader in pathology, has been constituted professor of pathology so long as he holds the readership in question.

AT the recent congregation of the University of Leeds a fellowship of the value of 100*l.* was awarded to Mr. Joseph Marshall, of the Victoria University School of Chemistry.

PROF. STEPHEN M. DIXON, holder of the chair of civil engineering in the Dalhousie University, Nova Scotia, has been appointed to the new professorship of civil engineering in the University of Birmingham.

IT was mentioned by the principal of King's College, London, at the recent distribution of prizes and certificates to the successful students that Prof. W. G. Adams, F.R.S., is about to resign his chair after forty-two years' work in the college.

THE Rogers prize of 100*l.* of the University of London has this year been awarded to Dr. B. J. Collingwood for his essay on "Anæsthetics, their Physiological and Clinical Action." The essay submitted by Dr. A. G. Levy was highly commended, and an honorarium of 50*l.* was awarded him.

A MOVEMENT is now in progress for providing the North Wales University College with new buildings at an estimated cost of 175,000*l.*, of which 30,000*l.* has been already promised. The site has been given by the corporation, which has presented the deed of gift to Lord Kenyon, president of the college. The president has expressed the hope that the rest of Wales will follow the liberality shown at Bangor, and that there will be no more need for the best professors of the college to leave Bangor for more lucrative positions in other parts of the United Kingdom.

ACCORDING to the *Electrician*, a committee of the Liverpool City Council, instructed by the Finance Committee to report as to how far the educational methods employed at the Liverpool University were in the interests of the city and met its requirements, have reported that they are satisfied that the University is doing its best to ensure that its students shall enter into the business of life with their intellectual powers fully developed by providing the students with a wide range of duty and sound methods of instruction, and they have therefore recommended that the sum of 10,000*l.* should be granted during the present year upon the same conditions under which a similar grant was made for the first time last year. The report of the finance committee has come before the City Council and has been approved. Of the amount in question, 1000*l.* is devoted to scholarships for Liverpool men.

COPIES have been received of the *Johns Hopkins University Circular* containing the programme of courses for the session 1905–06, and of the Yearbook of the Armour Institute of Technology, Chicago, for 1905–06. The Johns Hopkins University will begin its thirtieth year of instruction next October. The work will be carried on

in three divisions:—The graduate department, in which arrangements are made for the instruction of advanced students in the higher branches of science and literature; the medical department, in which students (men and women) who have already received a liberal education are received as candidates for the degree of M.D., and in which doctors of medicine may attend special courses; the collegiate department, in which students receive a liberal education leading to a degree. The Armour Institute of Technology was founded in 1892, and the work of instruction was begun in September, 1893. Courses are now offered in mechanical engineering, electrical engineering, civil engineering, chemical engineering, fire protection engineering, general science, and architecture, and all lead to the degree of Bachelor of Science.

In the course of an address on degree day, July 8, at the University of Liverpool, Lord Derby, the chancellor, said that since they last met they had several new laboratories, some complete and some in progress. Another building, to be opened in November, will be for the study of natural history. They had also an extension to record of the chemical laboratories, to provide accommodation for the department of physical chemistry, and an addition to the existing department. This had been provided at an estimated cost of 10,500*l*., which the president of the council, Mr. E. K. Muspratt, had promised to contribute. Since they last met 10,000*l*. had been given by Mrs. Barrow, the borough of Birkenhead had given an annual grant of 500*l*., and a grant of 10,000*l*. had been received from the Liverpool City Council, 1000*l*. from the county of Lancaster, from Cheshire 300*l*., and from the borough of Bootle 500*l*. The sum of 1500*l*. had been given to endow a lectureship in memory of Sir William Mitchell Banks. Mr. E. Whitley had promised 1000*l*., and under the will of the late Mr. J. L. Bowes the University would receive a legacy of 8000*l*. for the benefit of the department of chemistry and other purposes. The company subsequently proceeded to the new electrotechnical laboratory, and Sir Joseph Swan formally opened the building, which he described as eminently suited for the purpose for which it was intended. The cost of the laboratory has been defrayed by a sum of 12,000*l*., drawn from the university fund, and the Lancashire County Council has contributed 1000*l*. towards meeting the more pressing demands for equipment.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 18.—"On the Chemical Mechanism of Gastric Secretion." By J. S. **Edkins**.

June 8.—"On the Application of Statistical Mechanics to the General Dynamics of Matter and Ether." By J. H. **Jeans**. Communicated by Prof. J. Larmor, Sec.R.S.

The object of the paper is to apply the methods of statistical mechanics to questions connected with radiation and the energy of the ether. An attempt is made to examine whether or not the modern theory of thermodynamics of radiation can be regarded as resting on sound dynamical principles. The result arrived at is that the use made of the second law of thermodynamics in this theory, in particular in the proof of Stefan's law, is one which cannot be justified, and hence that those parts of the theory of thermodynamics of radiation which are based upon the use of the second law must be regarded as unsound.

The problem is obtained in its simplest form by considering either a finite universe, or else a finite portion of an infinite universe, enclosed within a perfectly reflecting boundary. Let the number of degrees of freedom of the matter inside this boundary, neglecting the interaction with the ether, be N, so that there are 2N coordinates of the aggregate system which very nearly represent motion of matter only. The number N is known to be actually finite, although it may be supposed to be so large that the error involved in treating it as infinite will be negligible. Let the number of degrees of the ether be M, giving 2M coordinates to the aggregate system. If we suppose the ether to have an absolutely continuous structure, the number M will be absolutely infinite.

The energy of the 2M coordinates of the ether is expressible as a sum of 2M squares. The energy of the 2N material coordinates may, again neglecting small terms, be divided into kinetic and potential energy. The kinetic energy is expressible as a sum of N squares, namely, the sum of the three components of energy of each electron of which the matter is composed. Thus the total energy is expressible as the sum of $2M+N$ squares, plus an unknown potential energy of electrons. It now follows, as in the proof of the well known theorem of equipartition of energy, that after an infinite time the sum of any p of these squares stands to the sum of the remaining q squares in a ratio which is equal to p/q, subject only to the condition that p and q are large enough to be treated as infinite without appreciable error. Since 2M and N satisfy these conditions, it follows that the system tends towards a state in which the energy of the ether is infinite in comparison with the kinetic energy of the matter. In other words, there is a general tendency for the ether to gain energy at the expense of matter.

It is, however, obvious that our own universe is at present far removed from its final state, so that the study of this final state is of less interest than the study of the stages through which the final state is being reached.

In discussing the transition to the final state, a principle proved elsewhere ("The Dynamical Theory of Gases," chapter ix.) is of service. Suppose that a vibration of any dynamical system is influenced by an external agency. Then the principle in question asserts that the ultimate effect of this influence is infinitesimal, except when the external agency changes to a considerable extent in a time comparable with the period of the vibration. If the time of change in the external agency is n times the period of the vibration, where n is large, then the ultimate change in the energy of the vibration vanishes to the same order as e^{-n}, a quantity which soon becomes negligible as n increases.

Thus, if θ is some small interval of time, so small that the material system may be regarded as perceptibly unaltered through a time θ, then the change produced in the energy of ether vibrations of which the period is less than θ will be very slight. The energy of such vibrations may therefore be treated as though it were incapable of change, so long as our consideration of the system does not extend over a very long period.

The total number of modes of vibration of any enclosed or unenclosed piece of ether is, as has been said, either very great or infinite, but the number of vibrations of an enclosed piece of ether *of which the frequencies are below an assigned value* is finite. Thus, we can now suppose M replaced by some small number M′, and the value of M′ will be finite. So long as we limit our consideration of the system to a finite time, say a million years, we may regard the energies of the remaining modes of vibration as constant and very small. The ratio of ethereal to material kinetic energy is now $2M'/N$, a quantity which cannot be infinite and may be very small.

If θ is a small time satisfying the conditions specified, then the rate at which an ether vibration of high frequency p gains energy will involve a factor $e^{-p\theta}$, so that the time required for the vibration to acquire a perceptible amount of energy will involve a factor $e^{p\theta}$. This is, of course, only true when $p\theta$ is large. The energy of those vibrations for which $p\theta$ is not large is rapidly adjusted, and a state will soon be reached in which these vibrations have the share of energy allotted to them by the theorem of equipartition of energy. With the progress of time the energy of the remaining vibrations gradually becomes perceptible, until ultimately the final state is reached.

We cannot, however, realise in nature the boundary impervious to all forms of energy, so that it is important to consider whether these predictions have to be modified if the boundary, instead of being perfect, is simply as perfect as we can make it.

It is found that there is no longer any tendency for the energy of the matter, even after infinite time, to vanish in comparison with that of the ether inside the enclosure; the two tend to assume a finite ratio, although neither of the actual energies can be permanent, as the system

inside the enclosure is no longer a conservative system. This definite ratio between matter and ether, however, lends a meaning to the expression "radiation at a given temperature," at any rate so long as we are concerned with the same enclosure and the same enclosed matter.

Stefan's empirical law states that the radiation is proportional to the fourth power of the absolute temperature, and Bartoli and Boltzmann have attempted to raise the law to the level of a theoretical law.

Their argument rests fundamentally upon the application of Carnot's principle to the working of a heat engine, in which the working substance is the ether.

Carnot's principle is, in effect, identical with the second law of thermodynamics, and this in turn is a special case of a special proposition in statistical mechanics. In the present investigation the most general methods of statistical mechanics are used, and the conclusion arrived at is different from that of the second law. The general investigation ought, of course, to take precedence over the attempted extension of the special case. It is, moreover, easy to find the exact point at which the general argument parts company with that used in the special case. In the special case, we are dealing only with forms of material energy such that there is an easy and rapid transfer of energy to the final state. The increase of entropy indicates simply the tendency to move towards this final state, and Carnot's principle is seen to be a special case of this general tendency in which it is supposed that the working substance is at every instant in the final state appropriate to its energy at that instant. When the ether is in question, it is found that the transfer of energy to vibrations of short wave-length, instead of being infinitely rapid, is, in point of fact, extremely slow, so that we never have to deal with a final state at all.

Moreover, it has to be assumed for Bartoli's argument that the energy of the working substance is a function of only two independent variables, *e.g.* the temperature and the density. This is not true in the case of an engine in which ether is the working substance; the ether energy is the sum of a number of vibrations of different wave-lengths, and the number of vibrations which have to be included in this sum will depend on the nature as well as on the temperature of the matter with which the ether is in communication.

Again, in the proposed argument for Stefan's law, the piston of the pump forms a moving boundary for the ether. The action of such a pump would change the frequency of vibrations in the ether, and energy which at one instant belonged to a vibration of one period would, after passing through the pump, belong to a vibration of some entirely different frequency. The energy of the vibrations of high frequency no longer remains unaltered and very small, for there is a transfer of energy to these vibrations at every stroke of the pump. The system will rapidly assume the final state appropriate to the value of this total energy, and this is a state in which the energy of matter vanishes in comparison with that of ether. Thus Bartoli's proof might be applicable to a universe in which pumps of the kind assumed had an actual existence, but has no application to our own universe in which the vibrations of highest frequency do not come into play at all.

It now appears that in attempting to obtain a law of radiation in conformity with the analysis of the present paper, we shall not be able to use any method so general as that of the second law of thermodynamics. The whole question is not one of partition of energy, but of transfer of energy.

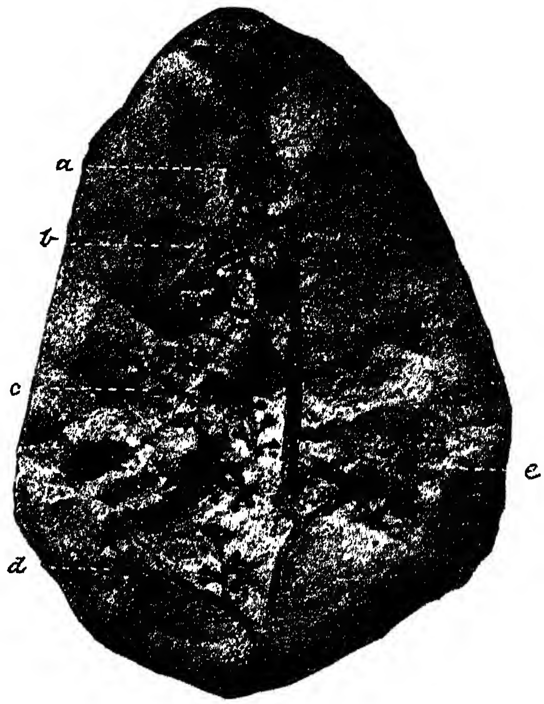
"The Microsporangia of Lyginodendron." By R. **Kidston,** F.R.S.

In a preliminary note a description was given of the microsporangia of *Sphenopteris* (*Lyginodendron*) *Höninghausi,* Brongt. It had been thought by some that the *Telangium Scotti,* Benson, might be the microsporangia of Lyginodendron, but the discovery of sporangia possessing all the characters of Crossotheca, Zeiller, in organic connection with the sterile foliage of *Lyginodendron* (*Sphenopteris Höninghausi*) shows that *Telangium Scotti* must belong to another plant.

The members of the genus Crossotheca (of which several species are known) had previously been regarded as *true ferns,* but now they must be classed with the Pteridospermeæ. The barren foliage of the species included in Crossotheca is very varied, and though the majority of the species possess sphenopteroid pinnules, one at least bears pinnules of the pecopteroid type.

In *Sphenopteris* (*Crossotheca*) *Höninghausi* each "fertile lobe bore six to eight broadly lanceolate sharply-pointed microsporangia. In the early condition the sporangia are bent inwards, and form a small hemispherical bunch with their apices meeting in the centre. At maturity the sporangia spread outwards, when they appear as a fringe hanging from the margin of the fertile pinnule, but are in reality connected for some distance to its lower surface. The microsporangia are bilocular, the parallel loculi being only separated by a narrow band of tissue. Dehiscence took place by a longitudinal cleft which passes down the inner surface of the sporangium in the line of the dividing wall of the two loculi."

The figure shows a penultimate pinna enlarged two



times. The ultimate pinnæ *c* and *d* bear sterile pinnules at their base, above which are some fertile pinnules. These latter, however, are better seen at *e*.

It has previously been shown by Prof. Oliver and Dr. Scott that the "seed" of *Sphenopteris Höninghausi* is the *Lagenostoma Lomaxi* of Williamson. *Sphenopteris Höninghausi* is thus the first pteridosperm of which the male and female organs are known.

The specimens described were derived from the 10-foot Ironstone-measures, Coseley, Dudley, which belong to the Westphalian series of the Coal-measures, and were communicated to the author by Mr. H. W. Hughes.

Royal Microscopical Society, June 21.—Mr. C. C. Karop, vice-president, in the chair.—Dr. **Lazarus-Barlow** exhibited and described a new form of warm stage, devised by him, that could be heated by oil or gas.—Mr. Cecil R. C. **Lyster** exhibited an improved form of warm stage, heated by electricity.—Mr. C. L. **Curties** exhibited an arrangement for obtaining dark ground illumination with high powers, which had been suggested to him by a contrivance made by Leitz for attaining this object. He showed *Pleurosigma angulatum* on a dark ground under a 1/12-inch oil immersion objective.—Mr. **Rheinberg** directed attention to an experiment showing that the ap-

pearance of a grating could be produced in the field of the microscope without there being anything on the stage. The lines seen were achromatic interference bands produced with the help of two of Thorp's gratings of equal pitch placed behind the objective.—Mr. **Rousselet** directed attention to a living specimen of *Plumatella punctata* (Hancock) sent by Mr. Hood, of Dundee. The rare freshwater polyzoon has apparently not been recorded in England since its discovery by Hancock in 1850. It differs from other species of Plumatella mainly in having a soft, transparent ectocyst.—A communication by Mr. E. M. **Nelson** on the tubercle bacillus was taken as read.—Mr. A. E. **Conrady** gave a *résumé* of his second paper on theories of microscopic vision. In his former paper he dealt with the formation of the image of a simple plane grating, showing that it could be fully accounted for on the basis of Abbe's theory. In the present paper he considered more complicated structures, such as dot- and cross-line patterns.

Geological Society, June 21.—Dr. J. E. Marr, F.R.S., president, in the chair.—The relations of the Eocene and Cretaceous rocks in the Esna-Aswan reach of the Nile Valley: H. J. L. **Beadnell**. At the meeting of the International Geological Congress held in Paris in 1900, the author brought forward evidence from the Baharia Oasis and Abu Roash to show that there was a marked unconformity between these two systems in the northern part of the country. The Jebel-Awaina succession shows that in the southern part of the country, where the Upper Cretaceous and the Lower Eocene occur in their fullest development, there is no sharp line of demarcation between the Cretaceous and the Tertiary, and no disturbances in the stratigraphical succession. This is confirmed by the succession in the Kharga Oasis, where there is no trace of an unconformity. Dr. J. Ball's conclusions to the contrary were mainly based on the supposed irregular variation of the Esna Shales; but, where this occurs, it is mainly due to the fact that, with a slight increase of carbonate of lime, these beds became almost indistinguishable from the overlying marls and marly limestones of the Eocene. The author finds in Jebel Nur el Ghenneiem some 180 feet of green clays between the *Echinocorys*-Chalk and the Eocene marls and limestones, and a perfectly conformable succession throughout. Near Ain Amur there is a considerable development of fossiliferous limestones at the summit of the Cretaceous rocks, and many of the fossils are hardly distinguishable from Eocene species. The author is of opinion that the Farafra succession falls into line with that which obtains in the southern part of the country. An important piece of confirmatory evidence is furnished by the discovery of a rich fauna in "ashen-grey clays" in the Esna-Aswan reach of the Nile Valley by Dr. W. F. Hume, in the clays above the *Pecten*-Marls in the neighbourhood of Esna.—A contribution to the study of the Glacial (Dwyka) Conglomerate in the Transvaal: E. T. **Mellor**. The survey of a district lying east of Pretoria and extending from near the diamond-fields to Middelburg has recently afforded much additional information with regard to the Glacial Conglomerate in this part of South Africa. The district lies on the northern edge of the principal area occupied by the Karroo system, and includes a number of outliers, the area between which affords information as to the source of the material of the Conglomerate and the character of the land-surface on which it was deposited. This surface is smoothed, grooved, and scratched by ice-action. The Karroo system is here only 400 or 500 feet thick, and the Conglomerate usually about 50 feet; but, where deposited in hollows, it may reach 200 feet or more in thickness. The fragments are usually from 1 to 3 feet in diameter, but may attain as much as 8 or 10 feet; they are often facetted and sometimes show striations. The majority of the boulders are of local origin. True bedding-planes are rare in the conglomerate, but there are included patches of sandstone, mudstone, or shale, some of which show ripple- or eddy-markings. The striæ are remarkably constant in direction, and they and the transport of boulders indicate an ice-movement from the north-north-west to the south-south-east. In the Prieska district Rogers and Schwarz found the movement to have been from north-north-east to south-south-west, and the same direction is given by Schenck from near the junction of the Orange and Vaal Rivers. During 1904 outliers of the Conglomerate were found farther north, near the junction of the Elands and Olifants Rivers.—On new Oolitic strata in Oxfordshire: E. A. **Walford**.—The causes of variegation in Keuper Marl and in other calcareous rocks: G. T. **Moody**. The author concludes that the variegation of the Keuper Marls and of other calcareous rocks has been brought about by the percolation of chalybeate water through the light-coloured mass, the more porous parts of which have in consequence become stained with ferric oxide, while the harder and more crystalline parts, being non-porous, have remained unchanged. The uniformity in distribution of ferric oxide in some red rocks, such as the New Red Sandstone, suggests that the iron contained in them has probably been derived from chalybeate water in a similar manner.

Challenger Society, June 28.—Dr. R. N. Wolfenden in the chair.—Dr. H. R. **Mill** exhibited the new chart of the world, recommended by the International Geographical Congress, and published at the cost of the Prince of Monaco. From 72° N. to 72° S. are sixteen sheets on Mercator's projection; each polar chart of four sheets is on a circular projection. The submarine contours and soundings are in metres, symbols indicating the bottom deposits. The land is black; the contours of the ocean are coloured in deepening shades of blue. Meridians (from Greenwich) and parallels are ruled for each degree.—Dr. W. T. **Calman** exhibited the two Decapoda brought from the Antarctic region by the *Discovery*, *Cranzon antarcticus* and *Chorismus antarcticus*, and explained their bearing on "bipolarity."—The **Secretary** showed a chart reproduced in line-process from one of the society's blank charts, in order to show the method of preparation.—On behalf of Messrs. E. W. L. **Holt** and W. M. **Tattersall**, Dr. Calman read a preliminary note on the Antarctic Schizopoda captured by the *Discovery*. The collection contained several new species of Euphausiidæ and Mysidæ, and the authors were able to show that *Euphausia superba* (Dana), Sars, *E. Murrayi*, Sars, *E. australis*, Hodgson, *E. glacialis*, Hodgson, and *E. antarctica*, Sars, are all referable to a single species.—The **Secretary** read a note on the probable time required by the larva of an epibenthic animal to cross the Atlantic, and made some remarks on the desirability of revising the nomenclature of ocean currents on an international basis.

PARIS.

Academy of Sciences, July 3.—M. Troost in the chair.—The theory of algebraic surfaces: **Émile Picard**.—The propagation of waves along a liquid compressible column, composed of strips of unequal velocities and filling an elastic horizontal tube, without longitudinal tension: J. **Boussinesq**.—On camphoacetic and β-camphopropionic acids: A. **Haller**. Methyl camphocarbonate heated with sodium methylate and iodoacetic ester gives methyl carboxymethylcamphoacetate, which, with alcoholic potash, furnishes camphoacetic acid. A corresponding compound is obtained by substituting ethyl β-iodopropionate for the ethyl iodoacetate in the original reaction, and from which β-camphopropionic acid is obtained.—On the existence in the black elder of a compound furnishing hydrocyanic acid: M. **Guignard**. The number of plants from which hydrocyanic acid can be obtained is increasing every year, and it has been suggested that it represents the first recognisable product of the assimilation of nitrogen in plants. In the elder, the fresh leaf furnishes the largest proportion of the acid, averaging 0·01 per cent.—Synthesis of the three tertiary dimethylcyclohexanols and of the hydrocarbons connected with them: Paul **Sabatier** and A. **Mailhe**. The cresols are converted into methylcyclohexanones by means of the reduced nickel reaction, and these are converted by methylmagnesium iodide into the corresponding tertiary alcohols, good yields being obtained. The preparation, physical properties, and reactions of the ortho-, meta-, and para-tertiary alcohols are described.—On the evolution of the tertiary mammals. A reply to the observations of M. Boule: Charles **Depéret**. A controversial note dealing more especially with the ancestry of the horse and bear.—M. P. Curie was elected a member

in the physical section in the place of the late M. A. Potier.—On the specific inductive power of metals in the case of the calorific and luminous waves: André **Broca.** The author concludes that the hypothesis of the existence of a considerable specific inductive power for the metals, although perhaps not sufficient to explain all the optical properties of metals in detail, is at least no more in contradiction with the facts than the hypothesis of Planck that this specific inductive power is zero.—An apparatus for measuring the factors, penetration, and quantity of X-rays, and a radiophotometric totaliser: G. **Contremoulins.** Silver plates of varying thicknesses are fixed on to rotating sectors, and the effect of interposing these in the path of the rays upon a phosphorescent screen is noticed.—The magneto-optical properties of ionoplastic iron: L. **Houllevigue** and H. **Passa.**—A method for establishing coloured screens, destined to isolate certain groups of special radiations: F. **Monpillard.** A given weight of a colouring matter is diluted to a certain volume with an aqueous solution of gelatin, and this poured on to a glass plate of fixed area, thus giving an invariable weight of colour per square centimetre. The author has succeeded in producing screens giving a maximum of luminosity in the green (λ 530), yellow orange (λ 588), yellow (λ 500), and red (λ 630).—The preparation of binary compounds of metals by thermochemical reactions: A. **Colani.** Some examples of the application of aluminium powder for reduction at a high temperature; the products are usually contaminated with aluminium and sometimes with iron.—The constitution and properties of the aluminium steels: Léon **Guillet.** So long as the percentage of aluminium is below 2 per cent., there is no marked change in the properties of the steel. Up to 15 per cent. the aluminium enters into solution in the iron, the iron-aluminium solution thus formed not dissolving carbon.—Combinations of ferrocyanides and sulphuric acid: Paul **Chrétien.** Hydroferrocyanic acid, dissolved in sulphuric acid without any gas being evolved, forms a sulphonic acid of the composition $H_3FeCy_6(SO_3H)$. With fuming sulphuric acid another compound is produced, $FeCy_6SO_2$, the decomposition and reactions of which have been studied.—A modification of the initial quality of iron and steel used in the manufacture of rivets consequent on the heating required in fixing: Ch. **Frémont.** It is found that the metal, after being heated and cooled under traction, is improved in quality mechanically.—On the acid γ-aldehydes: E. E. **Blaise** and A. **Courtot.** The authors have been successful in obtaining these aldedydes in a pure state for the first time. An unsaturated acid is treated with bromine, the dibromo-acid formed heated, a bromo-lactone being then formed by the loss of hydrobromic acid. Hydrobromic acid is then removed from this by boiling with quinoline, and the lactone thus produced, hydrolysed with an alkali, gives the acid aldehyde required.—The synthesis of the lactone of erythric acid: M. **Lespieau.**—A new method of synthesis of the monoatomic and polyatomic alcohols: V. **Grignard.** This important synthesis has been achieved by the author by acting with organometallic derivatives of the type RMgX on the halogen derivatives of the mono- or poly-atomic alcohols. The reaction takes place in two stages,

$$RMgX + ClCH_2.CH_2.OH = RH + ClCH_2.CH_2.OMgX,$$

and this on heating gives with a fresh molecule of a magnesium compound

$$R'MgX' + ClCH_2.CH_2OMgX = MgX'Cl + R'.CH_2.CH_2.OMgX.$$

The action of water on this last substance gives the alcohol $R.CH_2.CH_2.OH$. Several examples of the application of this synthetical method are given.—On β-decahydronaphthylketone and β-decahydronaphthylamine: Henri **Leroux.**—Some new derivatives of the mesoxalic esters: Ch. **Schmitt.**—The action of ethyl iodide on sparteine: Charles **Moureu** and Amand **Valeur.** The reaction gives sparteine iodohydrate and two isomeric iodoethylates.—The densities of carbonic anhydride, ammonia, and nitrous oxide: Philippe A. **Guye** and Alexandre **Pintza.** The results for the densities of nitrous oxide and carbon dioxide agree with those of Lord Rayleigh within the limits of experimental error, 1/6000 to 1/19,000. Special precautions were taken in the case of ammonia to ensure the absence of amines, the result being 1/700 lower than the figure of M. Leduc. The limiting densities for these gases were worked out, and the atomic weight of nitrogen deduced as 14·006.—The thermochemistry of neodymium: Camille **Matignon.**—The influence of the elements of brown flour on the extraction of the gluten and bread-making: M. **Lindet** and L. **Ammann.**—On the cause of the withering of the vines in Tunis, Algeria, and the Midi: L. **Ravaz.**—On the presence of a hydrocyanic glucoside in the leaves of the elder, *Sambucus nigra*: Em. **Bourquelot** and Em. **Danjou.** The elder leaf contains a glucoside containing nitrogen, which, under the influence of emulsin, gives glucose, hydrocyanic acid, and an aldehyde.—Modifications and *rôle* of the segmentary organs in some annelids: Louis **Fage.**—On the epipodites of the Eucyphote Crustacea: H. **Coutière.** On the discovery of coal at Abaucourt (Meurthe-et-Moselle): René **Nicklès.** A layer of coal, 2·65 metres thick, has been found at Abaucourt, near Nomeny. It is at a depth of 896 metres, and on chemical analysis proves to resemble the gas coal of Saarbrück.—Observations on the preceding note: R. **Zeiller.**—On the geology of the Pre-alps in the neighbourhood of Jaen: Robert **Douvillé.**—Contribution to the tectonic of the southern Carpathians: G. M. **Murgoci.**—On the origin of lactose. The ablation of the mammæ in lactation: Ch. **Porcher.**—The fixation of chemical substances on living cells: MM. **Charrin** and **Le Play.**

THURSDAY, JULY 20, 1905.

ARCTIC METEOROLOGICAL OBSERVATIONS.

The Norwegian North Polar Expedition, 1893–1896; Scientific Results. Edited by Fridtjof Nansen. Vol. vi. Published by the Fridtjof Nansen Fund for the Advancement of Science. Pp. xiv+659; 20 plates. (London: Longmans, Green and Co., 1905.) Price 36*s*. net.

IT is a misfortune that meteorological results demand so many figures for their discussion, and so much space for their exhibition. Vol. vi. of the Norwegian North Polar Expedition, dealing with the climatology of the area through which the *Fram* drifted in its memorable voyage, 1893–6, is a most interesting book, but its size and appearance might repel any but the most ardent meteorologist. The discussion of the observations has been undertaken by Prof. Mohn, of Christiania, and the arrangement is a model of clearness and efficiency. Prof. Mohn superintended the whole meteorological equipment, suggested the plan of work to be carried out during the voyage, and arranged with Captain Scott-Hansen the general management of the meteorological work. We imagine Prof. Mohn must be gratified with the success of his arrangements, and the intelligent interest which the officers of the expedition have shown in the work. Notwithstanding the severity of the climate, there is hardly a gap in the series of observations. At sea, the observations were taken at intervals of four hours, but for the greater part of the time the readings were made every two hours, with a regularity that compels admiration. The result is that we have, with very considerable accuracy, the climatological elements of a region in the circumpolar Arctic Ocean, where the surface of the earth during the whole time was of a unique homogeneous nature, consisting of a level of frozen water, remote from continents and islands, and with an uninterrupted free horizon.

The wind, particularly with regard to direction and velocity, is the first element discussed. To obtain a sufficiently long series of observations for investigation, Prof. Mohn divides the interval into three groups, a dark season when the sun was below the horizon, a sunny season during which the sun was above the horizon for practically twenty-four hours, and the equinoctial months, during which there was regular day and night. The discussion shows that during the *dark* season the wind shifts generally against the sun. Only during four hours in the twenty-four does the wind veer with the sun, while in the *sunny* period the wind veers with the sun, backing about six hours, divided into periods of two hours each at three different periods of the day. In the equinoctial months the backing and veering are equal, the wind shifting with the sun during the night and morning, and against the sun from 10 a.m. to 10 p.m. The diurnal period of the wind's direction is a phenomenon which still awaits an explanation, and the different direction of the shift of the wind in the dark and in the sunny season seems to be of some importance for the solution of the problem. With reference to the velocity of the wind, it is shown to be greater when the sky is overcast than when it is clear. In the former case, the average velocity is 5.09 metres per second (11.4 miles per hour), and in clear weather only 3.54 metres per second (8 miles per hour). The greatest velocity recorded appears to be 40 miles an hour in February, 1896.

The discussions of the variations of temperature are very interesting, but the results drawn from them regarding the periods of the meteorological elements must of necessity be less trustworthy than if there had been a longer series of observations at disposal. It may therefore be premature to draw conclusions as to the connection between the different observed phenomena, and between those phenomena and their probable causes. The desirability of a longer period, and the character of the errors that can be introduced by the comparison of but few values, are shown very readily if we attempt to derive the month of lowest temperature from the figures given. The readings are centigrade, and show the mean temperature for each month:—

	January	February	March	April
1894	−35°.72	−35°.57	−37°.08	−21°.31
1895	−33.71	−37.18	−35.01	−28.89
1896	−37.33	−34.73	−18.89	−18.15
Mean	−35.59	−35.83	−30.33	−22.78

The great variation of temperature in March, 1896, making it nearly equal to that of April, demonstrates the uncertainty that must accompany any attempt to derive mean values from short periods. But the deductions drawn directly from the observations, and supported as they are in many instances by similar observations made in Arctic latitudes, are not liable to the same uncertainty. Among these results may be placed the following:—Throughout the dark winter months, when the sky is clear, the lowest temperature occurs in the *day*, the highest during the night. Generally, in the other months, we have the ordinary diurnal period. With the sky overcast, the diurnal period, with a minimum in the early morning hours and maximum after noon, is very well developed in all the months except January.

"The most striking feature," says Prof. Mohn, "seems to me to be the distinct diurnal period of the ordinary march in the winter and dark season, with the sky overcast and relatively higher temperatures. The inverted period with clear sky in the dark season seems to be due to the diurnal period of the wind's direction. The dark-season period with its stronger, south-easterly winds, is hardly to be accounted for by the radiation from the sun or sky."

The forms of cloud, the relative humidity, and the amount and character of precipitation are discussed at full length, but do not present results of unusual importance. With regard to the latter, however, it is not altogether uninteresting to notice that the number of days in a year on which rain is probable is 49, while snow may be expected on 157 days, and some form of moisture will be collected on 180 days.

Hail fell on only 5 days throughout the whole period. Rain can fall only from May to October, and July has the greatest number of rainy days, also it is the month which gives rise to the greatest amount of fog. Very considerable care was taken to determine the temperature of the Polar ice, but, naturally, much difficulty was experienced in recovering the thermometers from the bore-holes, in which they might be frozen fast, while during the summer, the viscous ice would close round them, requiring the thermometers to be dug out. Neither is it easy to remove the sources of error from the observations, especially from the effects of brine contained in the ice, which was apt to fill the bottom of the holes even during the coldest season, whilst during the summer all the holes were filled with briny or saline water, the salinity of which decreased inversely as the temperature. This brine percolated from a different level to that in which the thermometer was placed. In the winter time the temperature of the ice increased from the surface downward, and therefore the brine at the bottom of the hole was probably of too low a temperature. On the other hand, in the summer time, the ice near the surface was warmer than that lower down, and the brine would be less saline, and consequently lighter in the upper layers than in the deeper, so that in the summer time the temperature reading would again be too low. The result drawn from the observations is that the surface of the ice, in all months with the single exception of June, is warmer than the air. The difference is greatest in December, amounting to 16° F. The surface of the ice, being covered, except during a short time in summer, with snow, is protected from cooling by radiation upwards, and receives heat from the underlying warmer layers. This, no doubt, is the main factor in the explanation, though other causes are suggested by Prof. Mohn.

The book contains also an account of the meteorological observations made during the sledge expedition to Franz Josef Land in 1895–6. From this account we can quote only one remark, which illustrates the determination of the leader of the expedition to secure an unbroken series of observations.

"We had no lantern for the reading of the thermometer, and I tried in vain to construct one, which would not burn more oil than we could afford to use. But our eyes of course became gradually trained to see in the dark, and even in mid-winter, with no moonlight, there was so much light reflected from the snow that the column of the darkly coloured Metaxylol was dimly visible, and also the figures of the thermometer scale, but not the division marks."

Dr. Nansen therefore apologises for the absence of the decimal reading, which is missing about the time of new moon. The interest of the book is necessarily largely centred in the fact that the crew of the *Fram* laboured so diligently and so well to overcome the difficulties that were imposed upon them by the situation in which they were placed. To go up to the crow's nest to take additional readings of the instruments in dark, wintry weather seems to have been a source of positive enjoyment to those who took part in these observations.

EUROPEAN AND ASIATIC GEESE.

The Geese of Europe and Asia. By Sergius Alpheraky. Pp. viii+198; 24 plates. (London: Rowland Ward, Ltd., 1905.) Price 3*l*. 3*s*. net.

AT the present day most works on ornithology of a general character are of little permanent value because the broad outlines of the northern fauna have already been adequately dealt with. What we want, and what we so seldom see, are complete life-histories of separate groups of birds, adequately illustrated and described by ornithologists who are both well acquainted with them in the field and are capable of summarising their labours in an accurate scientific account. To do this a very large series of birds must be collected, examined and digested, and this means years of travelling and study with little monetary reward as the result. Nevertheless, the works of such men are of great and permanent value, although their costly nature must ever be a constant drawback to the producer. No good form of colour printing is cheap, and as this is a *sine qua non* in works of this kind, the results can only pass into the hands of a public "fit but few."

The latest of these monographs is that of "The Geese of Europe and Asia," by Mr. S. Alpheraky, and the Russian naturalist is to be congratulated in giving us the first detailed account of this interesting and, we may say literally, confusing group of birds. It is an admirable treatise, full of research in field and museum, and the work of one who has carefully studied the subject from all points of view. There are twenty-four coloured plates by Mr. F. W. Frohawk, which are unfortunately only moderately successful. Twenty-one of these represent the different kinds of geese described by the author, and for the most part the lithography is weak and hard, and evidently does not do justice to the artist's careful work; whilst the three plates representing the bills of four various kinds are excellent, and will be of the greatest use both to sportsmen and naturalists in the determination of species. The frontispiece to the work represents the assemblage of white-fronted and red-breasted geese on a sandspit, and is from the brush of Dr. Sushkin. The idea of movement exhibiting the various attitudes into which these birds throw themselves is very fairly represented, but the technical work of painting and the drawing of some of the wings, as well as the general composition, leave much to be desired. It seems a thousand pities that chromolithography is a dying art, and that no firm in Europe is capable of turning out first-class work except W. Greve, of Berlin. For all we know, these drawings by Dr. Sushkin and Mr. Frohawk may have been soft and truthful representations of nature, but here we only see hard and black lines such as nature never shows.

Mr. Alpheraky is evidently a keen sportsman as well as a good naturalist, and he rightly holds a high view of the remarkable intelligence of this class of birds.

"Geese," he says, "afford one of the most difficult kinds of fowling. However cunning man may be, he

finds it extremely difficult to over-reach these wary birds, and in some places one may see them in hundreds of thousands for several weeks at a stretch without the possibility of securing a single specimen. This is especially the case in thickly populated regions, where the geese already know that danger may threaten them."

By this we know that the writer has toiled and suffered many disappointments. In certain British waters where for three seasons Brent geese were abundant we never obtained more than one good shot with the punt gun in a season. This was generally at the commencement, when the birds arrived in late October. After this date we could only "look" and "long." Other species are equally cunning.

The key to genera, species, and subspecies with which the author furnishes us is an excellent compilation, although he does not make clear the difference between species and subspecies. For instance, it appears that full specific rank is accorded to *Branta bernicla, Branta bernicla glaucogaster,* and *Branta bernicla nigricans,* the three varieties of the Brent goose which visit our shores. If those which are furnished with trinomial names are intended to be subspecies, and it is a very doubtful point if they deserve even this distinction, the author should say so in his table. Personally we do not think that there is any reason for separating these three well marked varieties. We have killed all three from one flock, and visitors to the northern breeding-places of these birds have also found all three, as well as intermediate forms, breeding together on the same ground. If such splitting were to come into general use, endless new subspecies must be created amongst the goldfinches, crows, skuas, &c., and many other birds we could mention the slight local peculiarities of which afford small points of distinction. Neither is the author consistent in this respect, for he refuses to recognise "two geographical races, much less two species," of grey geese living in eastern and western areas, and also the American and European forms of the white-fronted goose as distinct. With regard to the bean goose, Mr. Alpheraky recognises three distinct races, *A. segetum,* the common bean goose, *A. arvensis,* which possesses white feathers at the base of the bill, and the eastern bean goose, *A. serrirostris,* a bird described by Swinhoe, which is larger, distinguished by its more massive bill. Another species closely allied to the last named, namely, *A. mentalis,* but which was first described by Przewalski in 1876, seems to be of very doubtful rank, and may be only a large form of the Siberian bean goose.

In this excellent monograph the author gives us all we wish to know about the difference of sexes, gradual growth from nestling upwards, plumage variation, moulting, local names, chase, and colour of the soft parts, the latter, perhaps, the most important point of all in the determination of species. Many excellent outline figures of the bills are also given, so that the reader has no difficulty in recognising the differences of the various races even if he feels inclined, as he must sometimes do, to question the necessity of specific separation.

To the oologist, too, the table and descriptions to be found on pp. 185–190, furnished by Mr. G. F. Göbel, are of the most exact and comprehensive nature, and the book is one that every working naturalist or wildfowler should possess in his library, for it is by far the best work that has as yet appeared on this interesting family of birds. J. G. M.

THE ELECTRIC FURNACE.

Le Four Électrique: son Origine, ses Transformations et ses Applications. By Adolphe Minet. 1er Fascicule. Pp. 76. (Paris: Librairie Scientifique, A. Hermann, 1905.) Price 5 francs.

THE application of electric heating to various metallurgical and other industries has of late been making very rapid progress. The time seems, therefore, to be well chosen for examining the various stages of development which the electric furnace has passed through.

M. Minet has taken great pains to collect together as much as possible of the available information, and has certainly succeeded in producing an interesting study. Chronologically, he divides his subject into three periods:—(1) laboratory furnaces (1808–1886); (2) industrial furnaces (1886–1890); (3) development of the industrial applications of the electric furnace from 1890 to the present day. The furnaces themselves are classified in nine groups, according to the function of the current and the method of its application. Any historical treatment of such a subject as this, which expects to be generally recognised as authoritative, demands very great care and judgment in its preparation. The present review certainly promises to be the most complete which the electric furnace has yet received.

It is, however, not so clear that the author has succeeded in accentuating just those developments which have been of the greatest influence to the general progress. There are no doubt difficulties in deciding between two such different claims as those of a brilliant invention and of a painstaking scientific investigation. The successful historian must, however, accurately estimate the value of each and decide on the relative merit according to the influence exerted by each upon subsequent development.

The classification of electric furnace processes is complicated, not only by the large number of separate cases which have to be considered, but more especially by the very different purposes for which the electric current is applied. In the first place it is necessary to distinguish between the purely electrothermal and the electrolytic functions of the current. The latter case embraces all such electrolytic methods as are carried out at a moderately high temperature. Here the electric current serves the double function of maintaining the necessary temperature and separating by electrolytic decomposition one or more of the constituents of the materials treated in the furnace.

During recent years the most extensive developments in electric furnace work have centred around the production and application of extremely high temperatures. The direct results of the scientific and

industrial discoveries along these lines have been very far-reaching. The success attending the investigation of various chemical reactions occurring at high temperatures has caused a marked revival in the interest taken in inorganic chemical research. This has been especially noticeable on the Continent, where, to a much greater extent than with us, the brilliant and rapid development of organic chemistry had led to a marked neglect of this older branch of the science.

The technical results are hardly less important. Several new and flourishing industries have been firmly established, some of them supplying hitherto unknown materials, which are proving themselves of great value in the arts. A still wider field of usefulness for the electric methods of heating seems now to be opening up. So far as the electrolytic and high temperature applications are concerned, there has been no direct competition with any existing technical processes. But now that the engineer and chemist have become familiar with the use of the electric furnace, there is a great tendency to extend its employment to work which requires temperatures already attainable by fuel heating if properly applied.

The possibility of generating the heat just where it is required, the ease of regulation of temperature, and the accompanying economy of heat losses, are the chief factors which tell in favour of electric heating under these conditions. The production of carbon bisulphide and the rapid development of the electrical manufacture of steel form excellent examples of what is being achieved technically in this direction; whilst even in the laboratory electrically heated tube and muffle furnaces are being largely employed in place of those heated by gas.

It is with the interesting details of such subjects as these that M. Minet is concerned. In view of the fact that this is but the first part of his complete work, it is impossible to do more than point out these main divisions of the subject. The author has drawn largely on the patent literature, and has copiously illustrated his descriptions with excellent diagrams and with the portraits of many of the leading investigators in this field of work. R. S. HUTTON.

OUR BOOK SHELF.

Elementary Microscopy. By F. Shillington Scales, F.R.M.S. Pp. xii + 179. (London: Baillière, Tindall and Cox, 1905.) Price 3s. net.

No instrument of research has such wide application in various branches of science and commerce as the microscope. It is, perhaps, scarcely too much to say that the principles underlying its construction and use are often disregarded by those who employ it, and sometimes totally ignored. Any treatise, therefore, on this subject, however unpretentious, is to be cordially welcomed, and the book now under notice is one that should meet a pressing need. It is written for beginners or for those who have used a microscope without troubling to understand it, and who consequently have never by any chance used it at its best.

The book commences with a description of various simple magnifiers and a descriptive diagram showing the essential parts of a microscope. These parts and the various accessories are in turn described more fully, as well as such appliances as are usually only found in the best instruments.

The most important points, such as substage condensers and fine adjustment construction, are treated somewhat fully. As to the choice of a microscope, reference is made to the fact that in medical schools and elementary science laboratories, where the cheaper form of instrument is usually provided, still no instruction is given as to its use, and that it is too often looked on as a mere magnifying glass. This is unquestionably true, and it is much to be deprecated that, in cases where the microscope performs such an important part in the work of instruction, no attention whatever is bestowed on its principles and use. The most interesting paragraphs in the book are, perhaps, those in which a comparison is made between the English and Continental stand. That the form of instrument now known as the English model is generally much superior in design and construction to the Continental stands is admitted and insisted on by the majority of those whose opinion is of value. At no period for many years past has the English microscope stand held such a high place, and it is greatly to be hoped that those who are in a position which gives them opportunities of recommending one form or another will recognise this. It is much to be regretted that, so far as objectives are concerned, the same cannot be said. Some English makers do undoubtedly produce lenses of good quality, but the average is not so high, and the finest objectives produced by Messrs. Zeiss are still unexcelled by those of any other makers. In the production of substage optical appliances, this country holds, as it has always done, a very high position, and it is difficult to understand why the same cannot be said of objectives. All the usual microscope accessories, as well as their method of use, are described as fully as the circumstances permit.

Chapters vi. and vii. are devoted to the practical optics of the microscope and its manipulation. This is the most important section of the book, and should be carefully studied. Perhaps more space might have been devoted to this, although it is quite easy to understand the difficulties that might arise in attempting anything like an exhaustive treatise on microscopic optics, debatable as the subject still is.

Altogether, the book is to be commended as a genuine attempt to treat the subject in a simpl straightforward manner, so that the reader for whom it is primarily intended may grasp its meaning without difficulty. J. E. B.

The Practical Photographer's Annual, 1905. Edited by Rev. F. C. Lambert. Pp. xxxvi + 160. (London: Hodder and Stoughton, 1905.) Price 1s. 6d. net.

THESE pages, as we are told in the preface, are intended to serve no other purpose than to aid the memory of the busy photographer, and if possible to anticipate his daily needs.

An examination of the book shows that the editor has very successfully accomplished his task, and at the same time has not made the volume of such a bulky nature as to render its size inconvenient. It is true that more references might have been inserted, but such an addition would perhaps be questionable.

The four sections into which the book is divided include a dictionary of practical hints, dodges, &c.; a collection of tables, weights, measures, everyday formulæ, &c.; a directory of the photographic societies of Great Britain and Ireland; and finally, a set of indices to the first twelve numbers of the present (library) series of the *Practical Photographer.* Each

of these sections is arranged so far as possible alphabetically, so that ready reference is greatly facilitated. We thus have a concise and practical dictionary which should be found of very general utility.

Murray's Handbook of Travel-Talk. Nineteenth edition. Pp. 688. (London: Edward Stanford, 1905.) Price 3*s.* 6*d.*

THAT this little pocket-book meets the requirements of travellers is shown by the fact that this is the nineteenth edition that has been issued. The success of such a companion depends mainly on the arrangement and scope of the material which it contains, and on these points it seems difficult to suggest any improvements. This edition is divided into fourteen distinct but comprehensive groups of subjects, each one containing exclusively those words and phrases which naturally belong to each section. Great pains seem to have been taken to bring the information up to date, motoring, for example, having quite a large part devoted to it. The Britisher is equally helped in either French, German, or Italian, and such a *vade mecum* as is here presented should be found of great service to everyone who crosses the Channel.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Pressure of Radiation on a Clear Glass Vane.

IN NATURE, June 29, a letter from Mr. G. F. Hull appeared under the above title. In it the writer claims to have verified experimentally that the pressure upon a transparent vane is equal to the difference in the density of energy in front of and behind the vane, and reference is made to a difference of views regarding the theory of the pressure in a non-absorbing medium.

In regard to the latter point, the same result is obtained for the particular case in question whether the beam of light is considered simply as a carrier of momentum or whether the pressure due to radiation is regarded as arising from a mechanical bodily force integrated throughout the material medium in which the radiation is being propagated. Consider the latter theory for steady radiation consisting of plane polarised waves of simple harmonic period $2\pi/\kappa c$ propagated along Ox (see Larmor, *Phil. Mag.*, vol. vii., p. 578, 1904).

We have

$$\frac{\epsilon}{c}\frac{\partial Y}{\partial t}=-\frac{\partial \gamma}{\partial x};\quad -\frac{1}{c}\frac{\partial \gamma}{\partial t}=\frac{\partial Y}{\partial x};$$

where ϵ is complex if the medium is absorbing.

The mechanical force per unit volume is directed along Ox and is given by

$$F=\frac{1}{c}\gamma\,.\,(\text{true current})=-\frac{\partial}{\partial x}\left[\frac{\gamma^2}{8\pi}+\frac{1}{8\pi\kappa^2c^2}\left(\frac{\partial Y}{\partial t}\right)^2\right].$$

If all the interfaces are perpendicular to Ox, then γ and Y are continuous throughout, whether the medium vary continuously or abruptly; consequently the mean value of the mechanical force upon any slice of the medium can be expressed as a pressure per unit area upon each surface equal in amount to the mean value of $(\gamma^2+Y^2)/8\pi$ at the surface. Thus for any vane suspended in free æther (or air) the resultant mechanical force is equivalent to a pressure per unit area equal to the difference in energy-density in front of and behind the vane.

The apparent confusion arises from the usual statement that the mean value of γ^2+Y^2 can only vary along Ox in the case of an absorbing medium, but this is true only for progressive waves. For a transparent medium of refractive index n conveying progressive and regressive waves the mean value of $(\gamma^2+n^2Y^2)/8\pi$, or the mean value of the energy density, is constant; but the mean value of $(\gamma^2+Y^2)/8\pi$ varies harmonically along the direction of propagation. For a plate extending from $x=0$ to $x=h$, and subjected to a normally incident beam of mean energy-density I, it can easily be verified that the mean value of $(\gamma^2+Y^2)/8\pi$ within the plate is equal to

$$I\{(n^2+1)^2-(n^2-1)^2\cos 2n\kappa(h-x)\}/\{(n^2+1)^2\sin^2 n\kappa h+4n^2\cos^2 n\kappa h\};$$

consequently the resultant pressure is equal to

$$2I(n^2-1)^2\sin^2 n\kappa h/\{(n^2+1)^2\sin^2 n\kappa h+4n^2\cos^2 n\kappa h\},$$

or equal to $2J_0I$, where J_0 is the normal reflecting power of the plate for the radiation used.

T. H. HAVELOCK.

St. John's College, Cambridge, July 14.

An Omitted Safeguard.

IN two schemes set out in a recent issue of NATURE, one dealing with the requirements of Oxford and one with the organisation of applied science in London, there appears a noteworthy omission.

If the weather is proverbially the first topic of conversation of Englishmen, it is surely because of the influence it has on the well-being of the community.

Yet in both the schedules referred to no provision is made for research in meteorology. It is singular how tardy is the recognition of so important a factor in the national welfare. It is to meteorology that we constantly appeal for help. By its daily survey of rainfall it safeguards our water supply (now a very anxious problem, being outpaced by the ever-increasing demands of population, sanitation, railways, or manufacturing machinery). We turn to it for the comparison of localities and to study the effects of climate or fog upon health and disease, or to ascertain the relations of temperature, sunshine, or rainfall to the prosperity of the crops and fruit gardens. We look to the readings of the barometer to protect the safety of those working underground. Meteorology takes cognisance of the force of the wind for the protection of structures, or of storms likely to imperil the mariner on his voyage, and by the extension of, and the improved modes of, forecasting the weather is becoming each year of greater service to all.

Without encroaching further upon the limits of your space, sufficient has perhaps been said to show *primâ facie* grounds (while so much is proposed to be devoted to physics, geology, or botany) for the consideration of a possible chair in meteorology, or for in some other way repairing an omission of so serious a kind in the schemes lately propounded. The large amount devoted annually to meteorology in the United States shows the appreciation of its utility to all classes of the community by so practical a people as the Americans, and that the outlay is amply recouped by the value of the services rendered by it.

RICHARD BENTLEY.

The Hydrometer as a Seismometer.

IN NATURE of June 29 Mr. Bennett discusses the motion of a floating hydrometer when vertical motion is imparted to the (rigid) vessel containing the (incompressible) fluid in which the hydrometer floats. The solution offered is that the whole system moves precisely as a rigid body would move, and this solution clearly satisfies the very simple equations of motion in the problem considered. But is such motion stable? In general it is not, and I believe that Faraday studied experimentally the "crispations" of a free surface of liquid when small vertical oscillations were imparted to the containing vessel.

This hardly affects Mr. Bennett's conclusion that a floating hydrometer is an unsatisfactory form of seismometer, but perhaps it may explain the positive results which some observers have obtained; elastic yielding of vessel or hydrometer, although conceivably an adequate explanation, is not the only one open to us.

Cambridge. C. V. BURTON.

NOTES ON STONEHENGE.[1]

VIII.—On the Dartmoor Avenues (*Continued*).

MY inquiries began at Merrivale because there is a circle associated with the avenues a little to the south of the west end of the longest; and again nearly, or quite, south of this there is a fine menhir, possibly used to give a north-south line. There is another menhir given on the Ordnance map, azimuth N. 70° 30′ E., which, with hills 3° high, points out roughly the place of sunrise from the circle in May (April 29). Although this stone has been squared and initialed, I think I am justified in claiming it as an ancient monument. There is still another, azimuth N. 83° E., giving a line from the circle almost parallel to the avenue. I hope some local achæologist will examine it, for if ancient it will tell us whether the N. avenue or the circle was built first, a point of which it is difficult to overrate the importance, as it will show the strict relationship between the astronomy of the avenues and that of the circle, and we can now, I think, deal with the astronomical use of circles after the results obtained at Stonehenge, Stenness and the Hurlers as an accepted fact. With the above approximate values the date comes out 1750 B.C., the declination of the Pleiades being N. 6° 35′.

I now pass on from Merrivale as an example of those avenues the direction of which lies somewhere in the E.-W. direction. Others which I have not seen, given by Rowe, are at Assacombe, Drizzlecombe and Trowlesworthy; to these Mr. Worth adds Harter or Har Tor (or Black Tor).

The avenues which lie nearly N. and S. are more numerous. Rowe gives the following:—Fernworthy, Challacombe, Trowlesworthy, Stalldon Moor, Batterdon, Hook Lake, and Tristis Rock. Of these I have visited the first two, as well as one on Shovel Down not named by Rowe, and the next two I have studied on the 6-inch Ordnance map.

Fernworthy (lat. 50° 38′).—Here are two avenues, one with azimuth N. 15° 45′ E., hills 1° 15′. There is a sighting stone at the N. end. We appear to be dealing with Arcturus 1610 B.C. This is about the date of the erection of the N. avenue at Merrivale.

The second avenue has its sighting stone built into a wall at the south end. Looking south along the avenue, the conditions are azimuth S. 8° 42′ W., hills 3° 30′.

Both these avenues are aligned on points within, but *not* at the centre of, the circle.

Challacombe (lat. 50° 36′).—This is a case of a triple avenue, probably the remains of eight rows, in a depression between two hills, Challacombe Down and Warrington. There is no circle. The azimuth is 23° 37′ N.W. or S.E., according to direction. The northern end has been destroyed by an old stream work; there is no blocking stone to the south on either of the remaining avenues, but one large menhir terminates one row of stones. The others may have been removed. So it is probable that the alignment was to the north. If so, we are dealing with the setting of Arcturus, warning the summer solstice sunrise in 1860 B.C. To the S. the hills are 4° 48′, to the N. 4° 50′.

To this result some importance must be attached, first, because it brings us into presence of the cult of the solstitial year, secondly, because it shows us that the system most in vogue in Brittany was introduced in relation to that year. In Brittany, as I have before shown, the complicated alignments, there are 11 parallel rows at Le Ménac (p. 99) (there *were* 8 parallel rows at Challacombe), were set up to watch the May and August sunrises, and the solstitial alignments came afterwards. The Brittany May alignments, therefore, were probably used long before 1860 B.C., the date we have found for Challacombe, where not the sun rise, but the setting star which gave warning of it was observed.

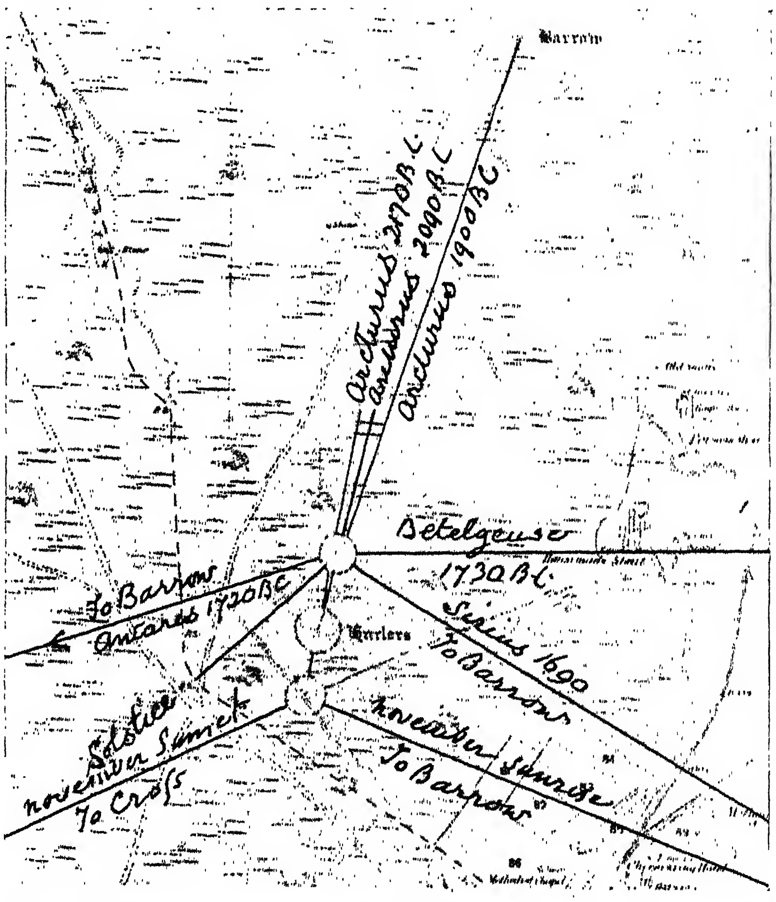

FIG. 20.—The sight-lines at the Hurlers, showing high northern azimuths among others. From the Ordnance map.

It is worth while to point out that at Challacombe, as elsewhere, the priest-astronomers so located their monuments that the nearly circumpolar stars which were so useful to them should rise over an horizon of some angular height. In this way the direction-lines would be useful for a longer period of time, for near the north point the change of azimuth with change in the declination of the star observed is very rapid.

Shovel Down, near Batworthy (lat. 50° 39′ 20″).—

[1] Continued from p. 248.

A group of five rows of stones, four double, one single, with two sets of azimuths.

One set gives us 22°, 25°, and 28°. They seem to be associated. I will call them A, B, and C. A is directed to the circle on Godleigh Common. Its ends are free. B is a single line of stones to the E. of the triple circle, about which more presently. It is not marked on the Ordnance map; its ends are also free. C has its south end blocked, I think in later times, by a kistvaen. The astronomical direction may be, therefore, either N.W. or S.E. We find, however, a probable use in the N.W. quadrant, as at Challacombe, Arcturus setting at daybreak as a warner of the summer solstice.

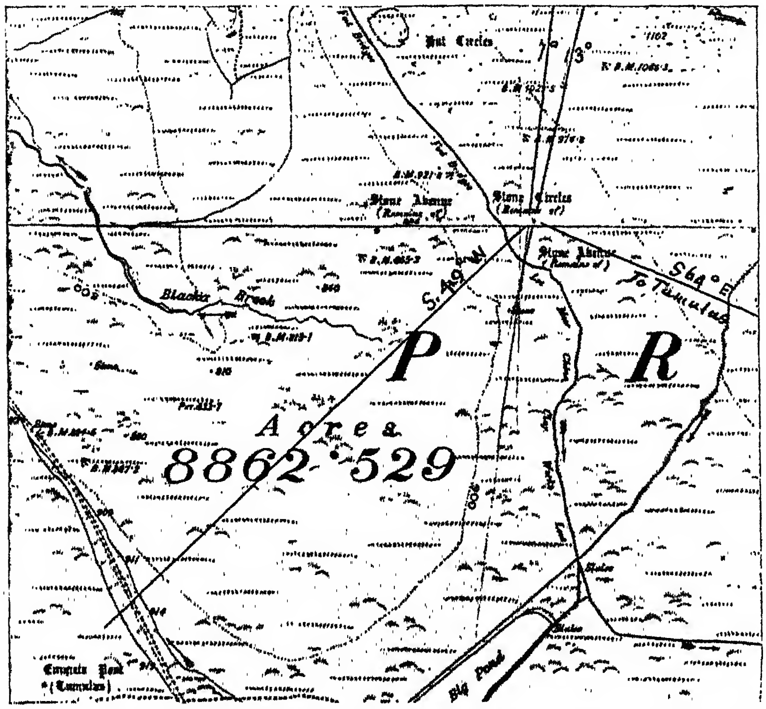

FIG. 21.—The sight-lines at Trowlesworthy, showing high northern azimuths among others. From the Ordnance map.

The height of hills is 46′; we have then :—

Az.		N. Dec.		Star		Date
		° ′ ″				
22	...	36 19 14	...	Arcturus	...	1210 B.C.
25	...	35 23 20	...	,,	...	1040 ,,
28	...	34 19 30	...	,,	...	850 ,,

Adjacent to A, B, C, is another avenue, which I will call D. Unlike the others, its northern end points 2° E. of N. Its southern end is blocked by a remarkable triple circle, the end of the avenue close to it being defined by two tall terminal stones. We are justified, then, in thinking that its orientation was towards the north; the height of the horizon I measured as 45′. It may have been an attempt to mark the N. point of the horizon.

The triple circle to which I have referred is not an ordinary circle. I believe it to be a later added, much embellished, cairn. According to Ormerod, the diameters are 26, 20, and 3 feet, and there are three stones at the centre.

All the above avenues are on the slope of the hill to the north. On the south slope we find the longest of all, as shown on the Ordnance map survey of 1885. There is a "long stone" in its centre, and at the southern end was formerly a cromlech, the "three boys." Part of this avenue, and two of the three "boys," have been taken to build a wall. The long stone remains, because it is a boundary stone!

The azimuth is 2° 30′ W. of north or E. of south. Looking N. from the long stone, the height of the horizon is 2° 30′. I think this avenue was an attempt to mark the S. point.

Trowlesworthy (lat. 50° 27′ 30″).—The remains here are most interesting. This is the only monument on Dartmoor in which I have so far traced any attempt to locate the sun's place at rising either for the May or solstitial year. But I will deal with the N.-S. avenue first, as it is this feature which associates it with Fernworthy and Challacombe, and in order that a comparison may be made I append a map showing the sight-lines at the Hurlers (Fig. 20).

As at Merrivale, the avenue has a decided "kink" or change of direction. The facts as gathered from the 6-inch map are as follows :—

	Az.	Hills	Dec.	Star	Date
		° ′	° ′ ″		
S. part o. Avenue	N. 7 E.	2 52	41 29 10	Arcturus	2130 B.C.
N. ,, ,,	N. 12 E.	2 52	41 6 20	,,	2080 B.C.

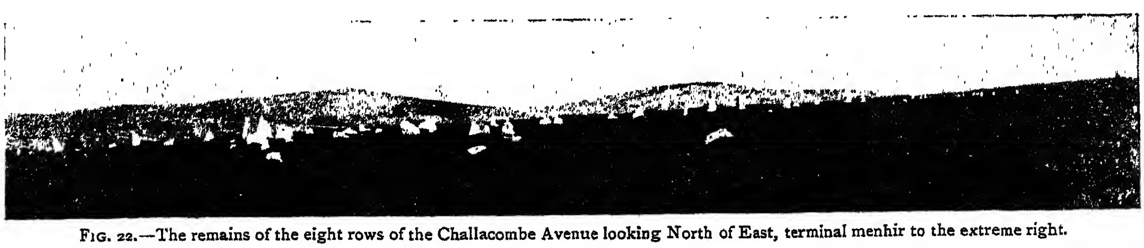

FIG. 22.—The remains of the eight rows of the Challacombe Avenue looking North of East, terminal menhir to the extreme right.

This date is very nearly that of the use of the S. circle at the Hurlers, and it is early for Dartmoor; but it is quite possible that local observations on an associated avenue a little to the west of the circle which terminates the N.-S. avenue will justify it. This is not far from parallel to that at Merrivale, but its northern azimuth is greater, so that if it turns out to have been aligned on the Pleiades its date will be some time before that of Merrivale, that is, before 1680 B.C. I can say nothing more about it until I have visited it.

The new features to which I have referred are two

tumuli which in all probability represent more recent additions to the original scheme of observation, as we have found at Stenness; and show that Trowlesworthy was for long one of the chief centres of worship on Dartmoor. Their azimuths are S. 64° E. and S. 49° W., dealing, therefore, with the May year sunrises in November and February and the solstitial sunset in December. It is probable that, as at the Hurlers, tumuli were used instead of stones not earlier than 1900 B.C.

Stalldon Moor (lat. 50° 27′ 45″) I have already incidentally referred to. The azimuth of the stone row as it leaves the circle, *not* from its centre as I read the 6-inch map, is N. 3° E.; as the azimuth gradually increases for a time, we may be dealing with Arcturus, but local observation is necessary.

The differences between the Cornish and Dartmoor monuments give much food for thought, and it is to be hoped that they will be carefully studied by future students of orientation, as so many questions are suggested. I will refer to some of them.

(1) Are the avenues, chiefly consisting of two rows of stones, a reflection of the sphinx avenues of Egypt? and, if so, how can the intensification of them on Dartmoor be explained?

(2) Was there a double worship going on in the avenues and the circles at the same time? if not, why were the former not aligned on the circles? On a dead level, of course, if the avenues were aligned on the centre of the circle towards the rising or setting of the sun or a star, the procession in the *via sacra* would block the view of those in the circle. We have the avenue at Stonehenge undoubtedly aligned on the centre of the circle, but there the naos was on an eminence, so that the procession in the avenue was always below the level of the horizon, and so did not block the view.

(3) Do all the cairns and cists in the avenues represent later additions, so late, indeed, that they may have been added after the avenues had ceased to be used for ceremonial purposes? The cairn at nearly the central point of the S. avenue at Merrivale was certainly not there as a part of the structure when the avenue was first used as a *via sacra* for observing the rising of the Pleiades. I have always held that these ancient temples, and even their attendant long and chambered barrows, were for the living and not for the dead, and this view has been strengthened by what I have observed on Dartmoor.

There was good reason for burials after the sacred nature of the spot had been established, and they may have taken place at any time since; the most probable time being after 1000 B.C. up to a date as recent as archæologists may consider probable.

Mr. Worth, whose long labours on the Dartmoor avenues give such importance to his opinions, objects to the astronomical use of those avenues because there are so many of them; he informs me that he knows of 50; I think this objection may be considered less valid if the avenues show that they were dedicated to different sacred uses at different times of the year. For instance, Challacombe is not a duplicate of Merrivale; one is solstitial, the other deals with the May year, and a complete examination of them—I have only worked on the fringe—may show other differences having the same bearing.

In favour of the astronomical view it must be borne in mind that the results obtained in Devon and Cornwall are remarkably similar, and the dates are roughly the same. Among the whole host of heaven from which objectors urge it is free for me to select any star I choose, at present only six stars have been considered, two of which were certainly used afterwards at Athens; and these six stars are shown by nothing more recondite than an inspection of a precessional globe to have been precisely the stars, the "morning stars," wanted by the priest-astronomers who wished to be prepared for the instant of sunrise at the critical points of the May or solstitial year.

NORMAN LOCKYER.

THE BOTANICAL CONGRESS AT VIENNA.

THE International Botanical Congress, held at Vienna on June 11–18, was an impressive demonstration of the activity of botany as a science, and of the enthusiasm of its adherents. Vienna is not the most central town for a meeting-place, but, nevertheless, more than six hundred botanists, men and women, representing nearly all the important, and many of the less important, botanical institutions of the world, met together there. As might have been expected, the central European element predominated, but there were a goodly number of Americans representing the southern and far western as well as the eastern States, while from the Far East came a deputation of two Chinese.

On the first day of the Congress, members were invited to be present at the opening of the Botanical Exhibition, which was held in the orangery of the historic Palace of Schönbrunn, just outside the town. The exhibition was an interesting one, and gave a good idea of the present position of botany from a teaching as well as from a more general point of view. There were fine series of diagrams, and coloured photographic lantern-slides of microscopic preparations, flowers, plant associations, and other objects; living cultures of Algæ; apparatus of all kinds; and some beautiful photographs of tropical vegetation in Brazil, Malaya, and elsewhere. A remarkable feature was the unique specimen of *Fockea capensis*, a member of the family Asclepiadaceæ, which, originally brought from the Cape, still remains the only known specimen. The plant has a hard, woody rhizome, as big as a child's head, from which in the rainy season numerous shoots are developed. It was figured and described by Jacquin in his "Fragmenta" at the beginning of the last century.

The Botanic Garden of Schönbrunn brings to mind, at any rate for the systematic botanist, the name of Jacquin, and some of his manuscript and original drawings were an important feature of the exhibition, and a subject of envious admiration of certain American botanists; we in London are proud to possess some of Jacquin's work, in the form of botanical letters to Sir Joseph Banks's librarian, Dryander, copiously illustrated with exquisitely delicate drawings. His herbarium, consisting largely of plants cultivated in the Vienna and Schönbrunn gardens, was bought by Banks, and is now in the general collection at the Natural History Museum. Nicolas Joseph Jacquin was professor of chemistry and botany at Vienna from 1768–96; later in the week of the congress a bust was unveiled in his honour in the Fest-Saale of the university. To quote from Prof. Wiesner's appreciation at the ceremony:—"His broad horizon and great powers of organisation were shown in the fact that, in the second half of the eighteenth century, no scientific, and especially no natural scientific, undertaking was started in which Jacquin did not take an important part. He embodied the ideal of the academic teacher." On the same occasion was also unveiled the bust of Jan Ingenhousz (1730–99), a Netherlander by birth, who spent the greater part of his working life in Vienna. Physician to the Empress Maria Theresa and the Emperor Joseph II., botanists know him best as one of the earliest workers in the sphere of plant

physiology; to quote the inscription beneath the bust, "Qua ratione plantae aluntur, primus conspexit."

On the evening of June 11, the members met in the Hall of the "Kaufmännscher Verein," when Prof. Julius Wiesner, the well-known head of the Institute of Plant Physiology, welcomed the botanists of the world to the home of Clusius, Jacquin and Unger; and the botanists renewed old friendships or made new ones over the Abendskarte and the inevitable *Bier*. At the official opening, in the great festal hall of the university, on Monday morning, greetings were given by the famous geologist and president of the Academy of Sciences, Prof. Eduard Suess, Prof. Wiesner, and others.

The general programme included lectures or papers by well-known men on topics with which their names have become associated. Thus Prof. Goebel discussed the subject of "Regeneration," and Dr. D. H. Scott gave an account of the present state of our knowledge of the Pteridosperms—the fern-like seed-plants of the Carboniferous flora—the illustration of which, by actual specimens, in the form of lantern-slides, was especially appreciated.

The development of the European flora since Tertiary times formed the subject of a group of papers. Prof. Engler, in stating the general problems, referred to the part played by man and his works, especially during the last century. He pleaded for the preservation of such plant-formations and plant-societies as throw a light on the past history of the European flora, citing as an example the National Park in the United States of North America. In the same connection Dr. Lauterbonn asked the help of the congress towards securing the preservation of part of the primitive forests of Bosnia, which, he stated, were in imminent danger of destruction. An interesting paper on the history of the development of the flora of the North German "Tief-land" was read by Prof. Weber. Covered by the sea since Oligocene times, this area became dry land during later Pliocene times, and the earliest vegetation of this period is remarkable for the occurrence of the vine, which is now generally regarded as an introduced plant in Central Europe. The plant-life of this area was, during the diluvial period, repeatedly crushed out of existence by land-ice, the intervening periods of vegetation being remarkable for the appearance of plants indicating a milder climate than do those composing the existing flora. Another subject, taken up by Dr. Molisch and Prof. Hueppe, of Prague, was the present state of our knowledge of CO_2-assimilation. Mention should also be made of a very fine series of photographic slides with which Dr. Hochreutiner, who has just returned from a prolonged stay in Buitenzorg, illustrated his account of a botanical institute in the tropics.

But for many of the members the most important work came in the afternoon, a time devoted by the majority to relaxation, which often took the form of excursions to places of botanical interest within easy reach of the town. Meanwhile the conference on botanical nomenclature sat in the lecture hall of the Botanic Gardens. At the entrance to the gardens is the former residence of the director, and we passed the window of the room in which Kerner wrote most of the well-known "Pflanzenleben." Kerner's successor, Prof. von Wettstein, is lodged in the new Botanical Institute—a large and well-arranged building. The arrangement of the gardens is mainly a geographical one—in one bed a collection of Himalayan plants, in another plants from the Cape, and so on. The result, though doubtless helpful to the student, illustrates the limitations to which such an arrangement is subject in any one climate. The work of the conference was to discuss the recommendations of the commission on nomenclature appointed by the International Congress of Paris in 1900. These were embodied in the *Texte synoptique*, a formidable quarto volume in which the *rapporteur général*, Dr. Briquet, had collated the numerous emendations and modifications of the original code of De Candolle, which during the last five years have been submitted by various societies, institutions, groups of botanists, and individuals. The numerous suggestions had previously been voted on seriatim by the members of the commission, and from the results of the voting certain recommendations were drawn up by Dr. Briquet for the consideration of the members of the conference, about a hundred and fifty of whom were present. The new American school was strongly represented by Dr. Britton, Mr. Coville, and others, while Dr. Robinson, of Harvard, represented the more moderate school which has worked on lines similar to those adopted in England. The Berlin school was present in force, and most of the Continental botanical societies and institutions were represented. As the president, Prof. Flahault, remarked, in answer to Dr. Otto Kuntze's protest against an "incompetent congress," it would be difficult to bring together a body of botanists more competent to discuss botanical nomenclature, and, one may add, more seemingly anxious to arrive at some solution of the various problems, and some agreement on the points at issue. From three to seven or eight o'clock each afternoon the members steadily worked through the *Texte*.

It was decided at the start to refer the question of cellular cryptogams and fossils to separate commissions, which should report to the next congress. The present conference, therefore, dealt only with flowering plants and vascular cryptogams. The results will in due course be arranged and published in English, French, and German. Brief reference may be made to the more important. The code of laws approved by the conference is based on that of De Candolle, and will consist of rules and recommendations, the difference between the two sets being expressed thus:—"A name contrary to a rule cannot be kept up; a name contrary to a recommendation is not a model for imitation but cannot be rejected." The most important result was the passing by an overwhelming majority of a list of generic names, which from long established usage are to be retained, though on the principle of priority they should be rejected. There was considerable discussion on the question as to the trivial name to be adopted when a plant is transferred from one genus to another, or from subspecific or varietal to specific rank. English, and a minority of American, botanists have followed the so-called "Kew rule" of adopting the first correct binominal, while the majority of American and most Continental botanists, in common with zoologists, adopt the earliest trivial name. On this point a compromise was effected as follows:—When a change of systematic position without change of rank occurs (such as the transference of a species from one genus to another), the earliest epithet is to be used; when the rank changes (as in the elevation of a variety to specific rank), the original epithet is not insisted on. The conference was also strongly opposed to any change in a name once given, though for various reasons it might be considered inappropriate or even misleading. A name is a name, and must stand.

An account of the congress would be incomplete without some reference to the nightly meetings for social intercourse which were arranged by the organising committee on typical Continental lines. Members will carry away very pleasant memories of the Rathhaus-Keller, the Prater, and the Brauerei garden out at Hutteldorf. For, after all, the great object of a

congress is the meeting together and getting to know one's fellow-workers; and an expression of thanks is due to the organising committee under the joint presidentship of Profs. Wiesner and von Wettstein, with Dr. Zahlbruckner as the energetic secretary, to Prof. Flahault, the firm and genial president of the conference on nomenclature, and finally to Dr. Briquet, whose name must always be associated with the latest attempt to solve the vexed question of plant-nomenclature.

At the final meeting, in response to an invitation from the Belgian Government voiced by Prof. Errera, Brussels was selected as the place of meeting for the third congress, which will be held in 1910.

A. B. RENDLE.

ENTRANCE EXAMINATION TO THE INDIAN FOREST SERVICE.

On May 11 the Secretary of State for India issued the regulations for the forthcoming entrance examinations for the Indian Forest Service. Amongst the features of these regulations two are of considerable importance.

The age limit is raised to twenty-one years on January 1 preceding the examination, so that the average B.A. who graduates usually between twenty-one and twenty-two may compete. The second point of interest is the schedule of the subjects in which he is to be examined.

According to the regulations given in the East India (Forest Service) Blue-book, Cd. 2523, the subjects in which the candidates are to be tested are four—chemistry, physics, botany, and zoology—and the schedules imply that the knowledge which the candidate is expected to exhibit is of a very limited description. Speaking roughly, the examination will be harder than the preliminary scientific examination which every candidate for a medical degree is obliged to take, but not much harder. Medical students generally pass their preliminary scientific examination during their first year, though there are cases in which they pass it while still at school. The Indian forestry students may pass their entrance examination in their third or fourth year. The Blue-book stated that each candidate must qualify in all four subjects, but for some reason or another—and probably because the entry under the new regulations is small—the Secretary of State for India has now still further lightened a very elementary examination, and is now advertising in our columns that zoology is optional. Thus men, who may be graduates, will be admitted into a great public service on an examination which comprises but three out of the ordinary four subjects which candidates for medical degrees normally pass in their first year, and judging by the schedules the amount in each subject to be "got up" is little more than in the preliminary examination for an M.B. degree.

When we remember that in the Indian Civil Service examination the standard of the subjects is that of an honours examination, and that a candidate takes not three subjects, but eight, nine, ten, or more, it is obvious that the Secretary of State is trying to recruit the forest officers from men of a markedly inferior intellectual range, and the strictures which were passed by Sir George King on the Indian foresters at the Dover meeting of the British Association will probably need repeating a few years hence.

The schedules are well adapted for an elementary pass or plough examination, but are ill adapted for a competitive examination. It will be very difficult, if not impossible, to select the best candidates competing in an examination carried on on these lines.

NOTES.

An important step in the direction of the adoption by this country of a decimal system of weights and measures has been taken by the Board of Trade. In reply to a resolution sent to the Board of Trade by the secretary of the Association of Chambers of Commerce, in which the Board was asked to authorise weights of 20 lb., 10 lb., and 5 lb. as aliquot parts of the cental, Lord Salisbury has written:—"With reference to your letter of March 14 last, in which you suggest that new denominations of weights of 20 lb., 10 lb., and 5 lb. should be legalised for use in trade, the Board of Trade have given careful consideration to the representations which have been made, and they are prepared to assent to the application. Steps will, therefore, be taken for the preparation of standards of the same octagonal form as the present 50 lb. weight." The chambers consider that this concession will save time, labour, and expense, as the 50 lb. weight has done already.

Commander Peary sailed on Sunday last to make a further attempt to reach the North Pole. Before leaving, he communicated various particulars respecting his expedition to Reuter's Agency. His plan is based upon the Smith Sound, or "American" route to the Pole, and his object is to force his ship to a base within 500 miles of the Pole itself, and then to sledge across the Polar pack. The Arctic ship *Roosevelt*, which has been specially built for this expedition, has been constructed so as to withstand the heavy ice pressure, and is so shaped that the pressure of the ice pack will have the effect of raising the vessel out of the water. The ship will carry a wireless telegraphic outfit, which, with one or two relay stations in Greenland, will keep her in communication with the permanent telegraph station at Chateau Bay, Labrador, and thence by existing lines with New York. By the same means communication with the expedition will be possible, at least for a portion of the distance, when in February next the sledge party leaves the *Roosevelt* for the northern dash. The ship will carry two years' supplies. With regard to the route to be followed, it is intended to establish a permanent sub-base at Cape Sabine, on the west coast of Smith's Sound, and, after securing the services of the necessary Eskimos, to force the vessel through Kane Basin and Kennedy and Robeson Channels to the northern coast of Grant Land or of Greenland, if the conditions should compel it, and there winter within 500 miles of the Pole. From these winter quarters a start north over the Polar pack will be made in February. The explorers will have available a probable period of five months in which to traverse the distance between their vessel and the Pole. In the event of the failure of the *Roosevelt* to force Kennedy and Robeson Channels during the first summer the dash for the Pole will have to be postponed until February, 1907.

The seventy-third annual meeting of the British Medical Association will take place at Leicester from July 24 to 28. Addresses in medicine and surgery will be delivered respectively by Dr. H. Maudsley and Mr. C. J. Bond, and, following the precedent of last year, a popular lecture will be given (on July 28) by Prof. Wm. Stirling, who will take as his subject the phenomena of fatigue and repose.

The Geologists' Association announces an excursion to Central Wales extending from July 24 to 29. The headquarters are to be at Llandrindod Wells.

The first International Congress of Physiotherapy will be held at Liége from August 12 to 15 next. The questions proposed for discussion are, says the *British Medical*

Journal:—(1) the specific indications of the several physiotherapeutic agents; (2) description of the apparatus and technique required in each case; (3) (*a*) how university teaching on physiotherapy is given at the present time in the various countries where instruction is given on the subject; (*b*) how such instruction should be given in medical faculties; (4) the indication of suitable means for the vigorous repression of quackery and the abuses caused by "healers" who pretend to treat by physiotherapeutic procedures. Papers should be sent to Dr. Gunzburg, 7 Rue des Escrimeurs, Antwerp.

THE full programme of the International Congress on Tuberculosis (meeting in Paris from October 2 to 7 next) has now been issued, and is summarised in the *British Medical Journal*. In the section of medical pathology, presided over by Prof. Bouchard, the following subjects are proposed for discussion:—(1) treatment of lupus by the new methods; (2) early diagnosis of tuberculosis by the new methods. In the section of surgical pathology, presided over by Prof. Lannelongue, the following questions will be considered:—(1) comparative study of different forms of tuberculosis; (2) ileo-cæcal tuberculosis; (3) surgical interventions in tuberculosis of the meninges and encephalon; (4) tuberculosis and traumatism. In the section of protection and assistance of childhood, presided over by Prof. Grancher, the questions to be discussed are:—(1) family protection; (2) protection in the school; (3) seaside sanatoriums; (4) school mutual aid societies and the part played by them in the prevention of tuberculosis. In the section of protection and assistance of adults, and social hygiene, attention will be directed to:—(1) etiological factors of tuberculosis, economic conditions in the social etiology of tuberculosis; (2) assurance and friendly societies in the prevention of tuberculosis; (3) the part of dispensaries and sanatoriums in the struggle against tuberculosis; (4) sanitation and healthiness of the dwelling; (5) hygiene of tuberculous persons in factories, workshops, places of business, army and navy; (6) disinfection of the dwelling of the subject of tuberculosis (administrative regulations and practical measures). In connection with the congress there will be an exposition arranged in the four following departments:—(1) scientific: a museum of microbiology, experimental, medical, surgical, and veterinary tuberculosis; (2) social: ravages caused by tuberculosis, prevention, assistance; (3) historical: tuberculosis in various ages, in art and in history; (4) industrial: prevention, alimentation, private dwellings, public dwellings (schools, barracks, &c.); travel (railway carriages, ships, hotels); assistance (hospitals, dispensaries, sanatoriums).

THE Museums Association held its annual meeting last week at Worcester; the proceedings opened on Tuesday, and on Thursday the president (Lord Windsor) delivered his address.

A TABLET to the memory of Sir Humphry Davy was unveiled by Mr. Marconi at Clifton, Bristol, on Friday last. The tablet is to be placed on 3 Rodney Place, Clifton, in which house Sir Humphry Davy lived for a time.

PROF. GUIDO CORA has been elected a member of the Pontificia Accademia Romana dei Nuovi Lincei of Rome.

WE regret to see the announcement of the death, on June 29, at Washington, of Mr. George H. Eldridge, one of the geologists on the staff of the United States Geological Survey. He contributed many valuable papers to geological science, dealing with coal, petroleum, asphalt, and bituminous rock deposits.

THE death occurred on July 10 of Sir Peter Nicol Russell, who, by his gift of 100,000*l*., founded the school of engineering of Sydney University. He was eighty-nine years of age.

THE death is announced of Mr. Charles Moore, director of the Sydney Botanic Gardens and of the Government Domain and Plantations. He had attained the age of eighty-six years.

A MEETING of the central committee for physical education in Italy took place recently in Rome under the presidency of Mr. L. Lucchini. Among those present were the Italian Under-Secretary of State for Instruction, and delegates of the Ministries of Instruction, War and Marine; there were also representatives of the municipality of Rome, the gymnastic association, and the Alpine and touring clubs of the city. The main object of the committee is to stimulate interest in the physical education of the Italian people, which, it is contended, has hitherto been much neglected.

A REUTER telegram from Penang states that the Chinese Consul of that place has offered to build and equip a Pasteur institute for the Straits Settlements and the neighbouring regions. The action has been prompted by the recent outbreak of rabies in Penang, resulting up to the present in four deaths.

BOTH Messrs. Siemens and Halske, of Berlin, and the Marconi Company are in communication with the Althing, the proposal being to establish communication by wireless telegraphy between Iceland and the Continent and internally in the island. According to a Reuter telegram, the Berlin firm offers to provide the installation for about 36,666*l*., and to guarantee the efficient working of the system.

IN connection with an exhibition to be held next year at Milan, there is to be a competition of appliances designed to safeguard against accidents, and the following prizes will be offered:—a gold medal and 320*l*. for a new device which will suppress the danger to life coming from a contact formed between the primary and secondary circuits of an electric transformer; a gold medal and 40*l*. for a crane or hoist provided with a simple and practical device preventing the rotation of the cranks on the descent of the load; a gold medal and 20*l*. for a simple, strong and effective apparatus for automatically stopping cars which are moving upon an inclined plane in case the traction cable should break; a gold medal for a practical device for exhausting and collecting the dust formed during the sorting and cutting of rags by hand; a gold medal for an apparatus for localised exhaust and successive elimination of dust produced during the cardage of flax, tow, hemp, jute, &c.; and a gold medal for an effective device to prevent the diffusion of dust in places where the preparation of lime and cement is carried on. The competition is to be under the auspices of the Association of Italian Industries, and names of competitors must be sent to the secretary at Foro Bonaparte 61, Milan, before the end of the present month.

A NUMBER of prizes ranging in value from 10,000 marks to 750 marks are offered by the Internationales Arbeitsamt, Basel, Switzerland, for essays on means of combating lead poisoning. The essays must contain proposals for the elimination of the danger to which no objection can be made on technical, hygienic, or economic grounds. In proposing new apparatus or alterations in process, particulars must be given as to the cost and saving involved in such proposals. It is desired that proposals should be

made for the improvement of existing laws upon the subject in all countries, and attention directed to the alterations which would be necessary for putting the suggestions into effect. The papers, which may be in English, French, or German, must reach the Internationales Arbeitsamt by the end of the present year.

WE learn from *La Nature* that the annual prize of the French Society of Civil Engineers has been awarded for 1905 to two men of science—to M. Alphonse Tellier for his researches on motor navigation, and more particularly for his memoir on "Les canots automobiles à grand vitesse," and to M. J. Rey for his memoir on "Les turbines à vapeur en général, et plus particulièrement sur les turbines du système Rateau et leurs applications." The Alphonse Couvreux prize has been awarded to M. F. Arnodin for his work on trans-shipping bridges. The 1905 Giffard prize will be postponed until 1908.

AT the annual distribution of prizes at Guy's Hospital Medical School last week the new Gordon Museum of Anatomy and Pathology was open to inspection. The museum is, it will be remembered, the gift of Mr. Robert Gordon, who at the distribution of prizes was presented by the governors and medical staff with a replica in silver of the statue of Thomas Guy in the hospital square, together with a bound memorial volume signed by the Prince of Wales and all the members of the governing body. The specimens in the museum now number upwards of 12,000, and their re-arrangement and classification will, it is hoped, be completed within the next few months.

PROF. A. PENCK contributes an account of the progress made in the organisation and execution of the map of the world on a scale of 1 : 1,000,000 to the *Zeitschrift* of the Berlin Gesellschaft für Erdkunde. It appears that up to March of this year the four chief organisations—French, German, British, and Indian—had completed 69 sheets out of 437 planned. A sketch map shows the sheets completed and in preparation.

THE Canadian Department of Marine and Fisheries has recently published a valuable paper by Dr. W. Bell Dawson on the currents at the entrance of the Bay of Fundy and on the steamship routes in its approaches off southern Nova Scotia. The results are based on observations made by the tidal and current survey in 1904, and show that the movements of water are chiefly tidal in character, there being no marked general movement in any one direction.

THE report on the census of the Philippine Islands, taken in March and April, 1902, has recently been issued. It consists of four volumes, comprising three thousand pages, and is freely illustrated with statistical maps and diagrams. An excellent summary of this report, which includes papers on the climate and resources of the islands besides other statistical information, appears in the Bulletin of the American Geographical Society for May, from the pen of Mr. Henry Gannett.

ALMOST from time immemorial, in a zoological sense, the South American electric eel has been regarded as the type (and sole representative) of the genus Gymnotus, as *G. electricus*, and it is thus named in the "Cambridge Natural History." In a paper on the Gymnotidæ published in the *Proceedings of the Washington Academy* (vol. vii., p. 159), Messrs. Eigenmann and Ward revive, however, an old proposal that the *Gymnotus carapus* of Linnæus should be taken as the type form, and the electric eel referred to a genus apart. They even go so far as to exclude the latter species from the Gymnotidæ altogether—a proceeding which forcibly recalls the well-known saying with regard to the play of *Hamlet*. This is, indeed, in our opinion, one of those cases in which, whatever may be original rights in the matter, everything is to be gained by adhering to established practice. In the text the authors define the different genera they include in the Gymnotidæ, describing some of these for the first time.

IN another issue of the serial last quoted (*Proc. Washington Acad.*, vol. vii., pp. 27–157) Mr. W. F. Allen records observations on the blood-vascular system in the fishes of the group Loricati, that is to say, those constituting the families Scorpænidæ, Anoplopomatidæ, Hexagrammidæ, and Cottidæ. In view of the circumstance that it is at present impossible to determine whether certain features in the circulatory system of these fishes are primary or secondary, no inductions are drawn from the observations with regard to the classification of the group. Nevertheless, it is suggested that the blood-vascular system may eventually prove to have a value in the classification of families and genera, although it would be useless in the case of species.

WE have received a copy of a circular issued by the Concilium Bibliographicum of Zürich in regard to a proposed physiological bibliography. A card catalogue of literature of this description was commenced on July 1, in cooperation with the *Zentralblatt für Physiologie*, and the support of all interested in the matter is requested. To aid the scheme a committee was appointed at the sixth International Physiological Congress held at Brussels, the names of the members of which are given in the circular.

THE annual report of the Selborne Society, published in the July number of *Nature Notes*, points to a flourishing condition of that body, although more members are required if its work is to be still further developed. Mr. W. M. Webb has accepted the office of hon. treasurer, *vice* Mr. R. M. Wattson, retired. Special attention is directed in the report to the preservation and protection of places of antiquarian interest or natural beauty in the neighbourhood of London. Among these, the proceedings of the London County Council in attempting to "beautify" Golder's Hill are criticised. "What is required is to leave the place more alone, and so to give nature a chance in it. Efforts to make things appear rustic almost invariably end by making them look artificial, and this is especially the case at Golder's Hill."

IN our notice of Sir C. Elliot's description of the nudibranchs of the Scottish Antarctic Expedition the number of species should have been given as six in place of two. Four of these species are new, two, as stated in the original notice, forming the types of as many new genera.

IN a brief note published in the *Atti dei Lincei* for June 3 Prof. Cuboni notifies the appearance in the island of Sardinia, in the district of Sassari, of a peculiar and little known disease of the olive. This disease, which is known in Italian as "Brusca," entirely despoils the plant of its leaves and fruit, and is associated with the fungus *Stictis Panizzei*. This fungus has an altogether remarkable history. It was first observed and studied by De Notaris near San Remo in 1842, and twenty years later it was found at Spezia. Between the years 1863 and 1899 no mention is to be found of its occurrence, but it suddenly reappeared in 1899 in the neighbourhood of Lecce, causing great damage to the olives of the district. The study of a fungus for which apparently very special conditions of growth are necessary seems likely to give results of particular interest in vegetable pathology.

In the *Proceedings of the American Academy of Arts and Sciences* (vol. xl., No. 23) Mr. Gilbert N. Lewis makes a study of the auto-catalytic decomposition of silver oxide under the influence of heat. It is shown that the velocity of decomposition of the oxide at a constant temperature increases as the action proceeds, and, after passing through a maximum, falls gradually to zero. The phenomenon is due to the catalytic action of the metallic silver produced, the action proceeding very regularly according to an equation representing the simplest case of autocatalysis. During the decomposition, definite temperatures between 327° C. and 353° C. were maintained by means of a thermostat containing a fused mixture of sodium and potassium nitrates. The purity and method of preparation of the silver oxide have a very great influence on the velocity of decomposition. The theory is advanced that the influence of the silver is directed in modifying the velocity of the reversible change $O_2 \rightleftharpoons 2O$.

We have received from the Medical Supply Association a pamphlet dealing with the Gaiffe auto-motor mercury-jet interrupter and its application in producing high-frequency currents. The interrupter is a simplified form of the mercury-jet turbine type, and is so arranged that the interrupter cuts off the current for both the motor and coil. The interrupter thus works automatically, and the use of an independent motor is dispensed with. The arrangement is simple, portable, and less expensive than any other form of turbine interrupter.

Some singular results obtained during the investigation of the activity of radiotellurium (polonium) are recorded by Prof. B. Walter in a paper in the *Annalen der Physik* (vol. xvii. p. 367). It would appear that the α rays of radiotellurium are capable of producing a species of fluorescence in the air through which they pass in such a manner that a radiation is set up having a pronounced photochemical action and similar properties to the ultraviolet portion of the spectrum lying between λ 350 and λ 290. The radiation is completely absorbed by aluminium foil 0·0091 mm. in thickness, but readily passes through a glass plate 0·15 mm. thick. In passing through a vacuum, however, the α rays of radiotellurium do not give rise to a radiation, whilst in gases other than air or nitrogen the effect is only very slight. The new radiation seems, indeed, to be produced only by nitrogen, the effect with this gas being thirty to fifty times as great as with hydrogen or oxygen. This fact is of unusual significance as tending to throw light on some of the peculiar properties of the nitrogen atom.

The part played by the copper salt in Deacon's process of preparing chlorine from hydrogen chloride is still uncertain, although many hypotheses have been put forward to explain it. That which has been most generally adopted assumes that cupric chloride is decomposed into cuprous chloride and chlorine, and that the cuprous chloride then undergoes re-conversion into the cupric salt under the influence of oxygen and hydrogen chloride, copper oxychloride being formed as an intermediate product. In an experimental investigation of the process published by M. G. Levi and V. Bettoni in the *Gazzetta* (vol. xxxv. p. 320) it is shown, however, that neither cuprous chloride nor the oxychloride can be used with a successful result in Deacon's process, and that the oxychloride is not convertible by hydrogen chloride into cupric chloride under the conditions in which chlorine is ordinarily formed. The hypothesis of an intermediate product is rejected and a purely catalytic action assumed, according to which the velocity of the change $2HCl + \frac{O_2}{2} = H_2O + Cl_2$ is greatly influenced by the presence of the copper salt. The catalyst is supposed to help the action by its tendency to combine with the water produced in the change.

An interesting article by M. Albert de Romeu on the industry of the abrasive materials such as corundum, emery, and carborundum appears in the *Revue générale des Sciences* for June 15.

No. 6 of vol. ii. of *Le Radium* contains a useful article by M. G. H. Niewenglowski on the development of photographic plates which have been subjected to the action of radio-active substances.

Under the title "From the Borderland between Crystallography and Chemistry," an address delivered before the Science Club of the University of Wisconsin by Prof. Victor Goldschmidt, of Heidelberg, is printed in the Bulletin of the university (No. 108). Attention is directed to the interesting results that have been obtained by studying the etch-figures and dissolution bodies of crystals and their significance in forming a mechanical theory of dissolution.

The sugar and cacao industries in the West Indies formed the principal subjects of discussion at the agricultural conference held in Trinidad in January; the proceedings in connection with these matters are reported in the first number of vol. vi. of the *West Indian Bulletin*. The condition of the sugar industry in Trinidad evoked considerable discussion, the subject at issue being the small amount of cane produced by the farmers per acre. Dr. F. Watts gave some account of the establishment of a well equipped central sugar factory in Antigua. The question of shade trees for cacao was debated, but evidence was not forthcoming to show why the shade that is considered necessary in Trinidad proves to be injurious in Grenada. Mr. L. Lewton-Brain and Mr. H. A. Ballou presented papers on the fungoid diseases and insect pests of sugar canes and cacao trees.

The route followed by Mr. B. Fedtschenko on his botanical journey through the Pamirs, as described in the *Bulletin du Jardin impérial botanique de St. Petersbourg*, vol. v., lay along the river Pianj where it runs parallel and a little to the north of the boundaries of Kashmir and Chitral; thence proceeding north the explorer returned to Osch, in Turkestan. *Anaphalis seravschanica* and *Ferula gigantea* were the most remarkable plants obtained on these stages of the journey. A malformation of the flowers of *Tragopogon pratensii* showing pedicelled florets and phyllody of the calyx is described by Mr. Dmitriew.

Mr. P. H. Rolfs presented the first results of his investigations into the diseases of citrous plants and fruits caused by the fungus *Colletotrichum gloeosporioides* in Bulletin No. 52 of the Bureau of Plant Industry, U.S.A. It is there shown that wither-tip, leaf-spot, anthracnose, and fruit canker are all due to the same fungus. Wither-tip and leaf-spot can be controlled by pruning followed by spraying with Bordeaux mixture, while spraying with ammoniacal solution of copper carbonate is efficacious against disease of the fruit. A later article in the *Florida Agriculturist* (March) deals with the appearance of these diseases on grape fruit.

The Jamaica *Bulletin of Agriculture* (May) contains an article by Mr. Fawcett on Raiffeisen agricultural banks, prompted by conditions which suggest that such a system could be advantageously introduced into the island. The

hurricane in August, 1903, caused such widespread devastation that the Government of Jamaica deemed it advisable to make temporary loans, thus assuming liabilities which would have been unnecessary had a cooperative system of borrowing money been in existence. In the same volume diverse opinions are expressed on the question of rotation of crops in connection with cotton cultivation in Jamaica. Cotton every third or fifth year, with intermediate crops of cassava or yams, maize, and legumes, is suggested; these rotations preclude the possibility of securing a second crop of cotton.

An instructive discussion of the law of biogenesis that "ontogeny repeats phylogeny" will be found in the paper forming Publication No. 30 of the Carnegie Institution of Washington, in which Mr. G. H. Shull bases his arguments upon a study of the leaf variation in *Sium cicutaefolium*. In the seedlings the first leaf after the cotyledons is extremely variable, the second leaf is generally simpler, but subsequently a pinnate leaf is developed which passes into a much dissected type. Well marked but less regular variations occur at periods of rejuvenescence and on the inflorescence. Mr. Shull concludes that ontogenetic leaf-characters afford no satisfactory clue to phylogeny, but that differentiation is due to the changed structure of the protoplasm.

"Perception in Plants" is the title of an article in *Naturwissenschaftliche Wochenschrift* (June), in which Prof. L. Kny discourses on *tropisms* and movements produced by other causes. Under heliotropism Prof. Kny mentions the views recently advanced by Haberlandt that the epidermal cells of a leaf are to be regarded as the perceptive region, and that their shape and contents enable them to act like a lens in collecting the rays of light. A photograph representing a surface view of the leaf of *Anthurium Maximiliani* tends to support this hypothesis, and also the observation that such a leaf, when submerged in water, fails to react.

We have received from Messrs. Flatters and Garnett, Ltd., 48 Deansgate, Manchester, slides exhibiting the structure of the root in the male fern and onion. They are remarkably good, and slides such as these will be of value to collections used for teaching purposes. The preparation of the material has been carefully attended to, and the details of cell and nuclear division are well shown.

Vol. i. of the report of the Royal Commission on London Traffic (appointed in February, 1903, to inquire into and report upon the means of locomotion and transport in London) has just been issued. It will be followed by seven more volumes, dealing respectively with the following subjects:—vol. ii., minutes of evidence taken, with index and digest; vol. iii., appendices to the evidence taken, and index; vol. iv., appendices to the report and index; vol. v., maps and diagrams furnished to or prepared by the Royal Commission; vol. vi., maps and diagrams furnished to the Royal Commission; vol. vii., report of the advisory board of engineers, and index; vol. viii., appendix to same.

The June issue of the *Bulletin de la Société d'Encouragement pour l'Industrie nationale* has been received. It contains a report, presented by M. A. Moreau on behalf of the Constructions and Fine Arts Committee, on "Ruberoid"; an account of a scheme for the extension of the international system to screws with a diameter of less than 6 mm.; and a paper by M. Maurice Alfassa on the organisation of labour in the United States. The economic notes, those on chemistry, and those on the mechanical sciences are as usual suggestive and interesting.

The *National Geographic Magazine* for July contains many interesting communications, among which are an address delivered to the National Geographic Society by Prof. E. A. Grosvenor on the "Evolution of Russian Government," an article entitled "The Purple Veil," the "veil" being the product of the *Lophius piscatorius*, known popularly as the "goose-fish," the "all-mouth," and the "angler," and a short paper (superbly illustrated) on "The Victoria Falls." The National Geographic Society, of which the magazine is the organ, is now housed under a deed of trust in the Hubbard Memorial Hall at Washington, the building being "in trust for the sole use and benefit of the said National Geographic Society so long, and for and during such period of time, as said Society shall continue its corporate existence under its present charter, and shall continue to use and occupy the said land and premises and the improvements thereon for the objects and purposes set forth in its certificate of incorporation."

The July number of the *Popular Science Monthly* contains an illustrated article on the University of Virginia, which, founded eighty years ago by Thomas Jefferson, has now as its first president Dr. E. A. Alderman. The illustrations contained in the paper show that the university possesses many buildings devoted to the teaching of science. Another article deals with Prof. C. A. Young, who, after more than fifty years' devotion to science, recently retired from the professorship of astronomy at Princeton University and the directorship of the Halstead Observatory.

In view of the approaching meeting of the British Association in South Africa, a special number of *Knowledge and Illustrated Scientific News* has been issued. It contains portraits of the president and of the presidents of sections, a programme of the proceedings, with a route map, and many articles dealing with South Africa and likely, therefore, to be of interest to those taking part in the association's meeting.

Mr. Murray announces "Noteworthy Families (Science)," by Mr. Francis Galton, F.R.S., and Mr. E. S. Galton. The work will form vol. i. of the publications of the Eugenics Record Office of the University of London. Another book to be brought out by Mr. Murray is "The Book of the Rothamsted Experiments," by Mr. A. D. Hall, the director of the Rothamsted Experiment Station.

Messrs. John Wheldon and Co., of Great Queen Street, Lincoln's Inn Fields, have sent us part i. of their new botanical catalogue dealing with Cryptogamia, and containing some 700 titles of books and papers.

Messrs. J. H. Dallmeyer, Ltd., have just issued their new list of photographic lenses, cameras, telescopes, prismatic binoculars, &c.

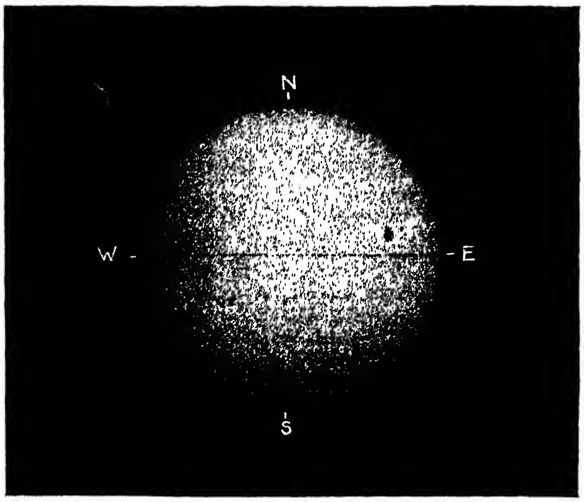
A second Italian edition of "Mattoni e Pietre di Sabbia e Calce," by M. E. Stöffler and Prof. M. Glasenapp, has been published by the firm of Ulrico Hoepli, of Milan. This edition is provided with eighty figures in the text and three folded plates at the end of the volume.

The second edition of "The Central Alps of the Dauphiny," by W. A. B. Coolidge, H. Duhamel, and F. Perrin has just been issued by Mr. Fisher Unwin. The work, which is one of the "Conway and Coolidge's Climbers' Guides" series, has been revised and brought down to the end of 1904, and the arrangement of the sections has to some extent been altered.

OUR ASTRONOMICAL COLUMN.

The Solar Activity.—The "maximum" character of the present solar-activity epoch is being well maintained by the frequent appearance of large groups of spots. Observations made on July 6 showed two medium sized spots coming round the eastern limb, and as this group travelled across the visible disc it developed considerably. On July 13 it formed a large and somewhat scattered group of which the roughly estimated extent was about 100,000 miles, and which could be readily seen by the properly protected naked eye. On July 10 this group was followed by a much more striking, although somewhat less extensive, group, consisting of two exceedingly well defined and large nuclei surrounded by well marked penumbræ and smaller spots. On July 14 both groups were readily observable with the naked eye, this being the second occasion during the present year on which two naked-eye groups have been on the solar disc simultaneously.

Single groups of this character have occurred four or five times since the first appearance of the large group in February. The accompanying reproduction shows the



forms and positions of the spots at 11.45 a.m. on Thursday last, and has been taken from a photograph secured with the photospectroheliograph of the Solar Physics Observatory, South Kensington, the primary slit being adjusted on the continuous spectrum instead of on any special line.

A Projection on Mars.—A telegram from Prof. Pickering, published in No. 4030 of the *Astronomische Nachrichten,* announces that on July 2 Mr. Lowell discovered a projection on the terminator of Mars. The object was situated near to Propontis, its position angle being 19°.

It may be remembered that in the first Bulletin issued from his observatory Mr. Lowell described a projection on the terminator of Mars, discovered by Mr. Slipher on May 25, 1903, its position angle varying from 204° to 200°. In that case the observations led to the suggestion that the projection was in reality a cloud of dust some 300 miles in extent which was travelling over the planet's surface at about 16 miles per hour (see Nature, No. 1763, vol. lxviii., p. 353, 1903).

Observations of Perseids.—Intending observers of the coming Perseid shower will probably find Mr. Robert Dole's account of his 1904 observations, published in No. 6, vol. xiii., of *Popular Astronomy,* of interest. During a total watch of 6h. 41m. on the nights of August 6, 9, 10 and 12, Mr. Dole, observing at Flagstaff, Arizona, saw 123 Perseids and 100 shooting stars, the horary rate of the Perseids being about 18·5. August 11 and 13 were completely cloudy, and consequently the observer was unable to determine the period of maximum of the shower. Some thirty of the apparent paths of the Perseid meteors were plotted, and are shown on a chart accompanying the paper.

The French Eclipse Expeditions.—Thanks to the liberality of the French Government and the activity of M. Loewy and his colleagues, French astronomy will be worthily represented amongst the expeditions which are going to, Spain, Algeria, and Tunis to observe the coming total eclipse of the sun.

Observers from the Paris and Besançon observatories will establish themselves near to Cistierna, in Leon, MM. Deslandres and Rayet are going to Burgos, whilst M. André (Lyons) will observe the eclipse at Tortosa.

The munificence of M. Bischoffsheim will enable the observers from Nice to carry out their programme on the coast near to Alcala, a station selected by M. de la Baume Pluvinel.

M. Trépied (Algiers) intends joining MM. Stéphan and Borrelly (Marseilles) at Guelma, Algeria, where MM. Nordmann and Salet (Paris) and MM. Bourget and Montangeraud, of the Montpellier Observatory, will also be located. M. Bigourdan will go to Sfax, where he intends to make actinometric observations with a Violle actinometer.

The director of the Paris Municipal Observatory, M. Jaubert, will also endeavour to make actinometric observations from the balloon *Centaure,* which is to ascend from Constantine, and a second Violle actinometer will be set up at that place for taking readings on the ground. Thermometric observations will be made on the ground and from a balloon at the Eiffel Tower, whilst actinometric observations will also be carried out at the Pic du Midi Observatory.

A Remarkable Meteor.—An unusually splendid meteor was observed by Dr. G. Johnstone Stoney on July 13.

The object was seen to traverse the eastern sky at 0h. 56m. a.m., and presented the appearance of an intensely bright and pure white globe having a diameter equal to about one-sixth of that of the moon. The meteor travelled in a N.E. direction along a path which sloped downwards, and which was nearly parallel to a line joining a point midway between α and β Andromedæ and β Persei at a distance from that line of about 12° measured along a great circle towards the south.

Dr. Stoney was not able to see the whole of the path followed by this brilliant object, but he saw it for some 30° or 35°, and estimates that his determination of the direction may be 2° or 3° in error, and of the distance of the apparent path from the reference stars, perhaps ±2°.

THE SOCIETY OF CHEMICAL INDUSTRY.

THE annual general meeting of this society was held at University College on Monday of last week. The council reported a total membership of 4326, an increase of 192 compared with the same period last year. It referred to the very successful meeting of the society in America last year, and to the pleasure felt at the visit to England of its American president, and a considerable contingent of American and colonial members. Statistics were furnished as to the number of original papers read before the various sections of the society, and reference made to the efforts of the society and its members during the year in connection with the use of duty-free alcohol for manufacturing and other trade purposes. The report of the hon. treasurer, Mr. S. Hall, indicated the continued prosperity of the society, though the cost of the journal had appreciably increased.

Mr. Gordon Salamon, chairman of the London section, next offered a welcome to the members of the society, and especially to the American and colonial members, on their assembling in London. The president then delivered his address.

Dr. W. H. Nichols, after expressing his obligations to Prof. Edward Divers, F.R.S., who had acted as deputy president during the greater portion of the year, alluded to the extension of the American membership of the society, which had been marked during his year of office by the

establishment of a New England section at Boston. He spoke of the advantage which resulted from the holding of regular meetings within reach of members as being a considerable addition to that ensuing from the possession of the valuable journal of the society, which he described as in itself worth many times the cost of membership.

Sir William Ramsay's presidential address of the previous year dealt with the results of thirty years' experience in the education of chemists, education being understood as the production of an attitude of mind rather than the imparting of definite knowledge, though the latter could not be neglected. Dr. Nichols considered the "attitude of mind" undoubtedly the pith of the matter. The young chemist fresh from college was only, after all, just prepared to learn how to apply the knowledge he had acquired, and to build on it by his daily experiences. As to some extent taking up the question where Sir William Ramsay laid it down, he proposed to discuss the question of the management of a chemical industrial organisation. The plan he proposed to outline, though it might differ widely from the views held by others as the result of their experiences, was the outcome of many years of observation and work, and had stood the test of years in a company operating more than a score of plants, widely separated and yet all working as a unit.

Below the board of directors, with its officers and executive committee, the following departments were necessary, viz.:—purchasing, sales, transportation, finance, construction, operating, research or investigation, and statistical. To harmonise these, two committees were requisite:—(1) a manufacturing committee, consisting of the managers of the operating, construction, purchasing, and investigation departments, the chairman being the chairman of the executive committee; and (2) a sales committee, composed of the managers of the sales, operating and purchasing departments, with a member of the executive committee.

The operating department was one of great complexity and importance, and needed a manager and assistant manager. Of the chemists employed, evidence is required not merely that they have received a good education and have completed a technical course of instruction, but that they are of good judgment and capable of assuming responsibility. It is desirable that they should have some knowledge of mechanical engineering and the general principles of construction, though in his experience so rare was a complete combination found that it was usually necessary to engage good chemists with but a moderate knowledge of engineering, or good engineers with only an elementary knowledge of chemistry. It was to be hoped, however, that as a result of the improved instruction in technical chemistry now being given, men would be turned out better prepared in this respect than had hitherto been the case. The great thing, however, was that the man should be practical, trustworthy, hard-working, and possessed of natural ability and the capacity for development and advancement, or, as Sir William Ramsay puts it, "have the right attitude of mind." The beginner should be kept long enough on one subject to make rapid and accurate analyses and at the same time be encouraged to make himself familiar with all the different methods of analysis bearing upon his particular work, and to be sure that he thoroughly understands the basic principles and theory upon which the work rests. After a sufficient experience along these lines, he arrives at a position where he may be able to improve existing methods or even invent new ones; but of course all new methods must be tested by rigid experiment.

In a works laboratory a variable degree of accuracy is required, depending upon the object for which the analysis is made. In some cases a tenth of 1 per cent. variation would not be serious. In other cases a ten-thousandth of 1 per cent., or even much less, is highly important, and as the object is to turn out analyses of the required accuracy in the least amount of time, it is of great advantage for the chemist to have such general knowledge of the use to be made of each analysis as will enable him to avoid waste of time in unnecessary accuracy. For routine work it is becoming more and more the custom to employ in works laboratories bright young men, graduates of high schools. Such young men are, of course, useful, but unless they pursue their scientific studies outside, as, for instance, at night schools, they are not likely to make great advances. In every laboratory there must be a chemist in control, who in turn shall be supervised by the chief chemist of the company. Unnecessary duplications being avoided, a force thus organised becomes capable of doing an enormous amount of work in a given time and with great accuracy.

The beginner confines his duties for a number of months, and frequently for years, to a works laboratory, and incidental to his analytical work he gains a certain knowledge of the general routine which obtains at that plant. After the laboratory service, if the chemist has displayed ability to advance, he is promoted to a position which will bring him into direct contact with the manufacturing processes, and his duties will gradually change from those of analyst to those of a manufacturing assistant, until he has become proficient enough to warrant promotion to the position of assistant superintendent, to which he is thereafter advanced at the earliest opportunity, either at the works at which he has received his tuition or at another works where such a position has become vacant.

The assistant superintendent is under the direction of the superintendent, and from him should receive a regular training in all the various duties pertaining to the position of superintendent, and when such a position becomes vacant, the assistant who, in the judgment of the department, is best qualified to fill the advanced position, is recommended for the promotion. The ability to administer chemical works can be obtained only by experience, and realising this fact the most efficient superintendents should act as teachers to the younger men in their development from one position to another.

Chemists who are not attracted by outside or works positions, but who prefer research work, naturally gravitate in due time from the works laboratory to the research laboratory. Occasionally one is found whose ambitions lie in the direction of mercantile affairs, for which he thinks the experience of the chemical laboratory will best qualify him. As a rule, however, the educated chemist does not select advancement in the sales department, or other business parts of the organisation, nor does it often happen that he is qualified.

The chemist, to succeed in technical work, must strive for material results. It has been my experience that the post-graduate course seems to incline him towards the search of learning rather than to its application. He must have a clear, logical mind, a singleness of purpose, and he must be able to separate the essential from the non-essential. This is true of all professions, but it is particularly true in chemical work, where the essential must be selected from an unusually large assortment of non-essentials.

The efficiency of a navy depends very largely on the "man behind the gun." So with chemists in a works or laboratory. The personal equation has much to do with the results. There is no "royal road" to success here. The rewards are for those who are willing to pay the price, and that price includes constant and intelligent work. The habit of study is rarely acquired after college days, and if the undergraduate does not develop it he should seek a less exacting profession than that of chemistry, unless his ambitions will be satisfied with the daily grind of routine work.

The investigation department is that part of the manufacturing organisation which deals with all the new propositions of a technical nature. Its work, which is entirely distinct from current manufacturing, has to do with new, and the improvement of old processes. A new proposition remains under the control of the investigation department from the time of its inception until sufficient data have been obtained to enable the construction department to design the necessary plant, if one be authorised by the executive committee. It is turned over to the operating department only after the process is working smoothly and the results considered satisfactory.

The organisation of the investigation department should be sufficiently broad to permit the consideration of a manufacturing proposition from the points of view of the business man, the chemist, the engineer, and the patent attorney. It consists of the manager, a chemical council composed

(in addition to the manager) of the chief chemical engineer, the chief chemist who is director of the research laboratory, and such consulting chemists and engineers as the company employs. The appointments in this council are intended to cover the most varied field of theoretical and technical chemistry, and the manager is permitted to consult outside experts if the company has not the necessary talent at hand. A corps of chemists on research laboratory work, an abstractor of current chemical literature, patent experts, and a small office force complete the department staff.

In the research laboratory a body of chemists, under the supervision of the chief chemist, is employed on research work connected with investigations in hand. A limited number of men are permanently retained on pure research work.

The research laboratory reports weekly the progress on all work in hand, and at the completion of each investigation sends in a statement of the steps taken, accompanied by the chief's recommendation as to further action. These reports are passed upon by the chemical council at its regular meetings.

All the analyses required are made by the analytical laboratory, which is specially equipped for turning out quick and accurate estimations. Each works has its own analytical laboratory, but there is a central laboratory for the work of the head office. This laboratory critically examines and selects all analytical methods, which are adopted as standards and furnished to all works laboratories.

The work of the investigation department originates from sources which may, in a general way, be divided into three classes:—

(a) The probability of reducing manufacturing costs.

(b) A decision to produce well established products not previously manufactured by the company.

(c) New applications of science to industry.

(a) The largest field is perhaps that of improving the processes at present in use at the different works, and is one which usually yields very profitable results. Aside from the chronic aim of the operating department to secure uniformly low costs, a decision to investigate a process in use may result from a drop in the market price of a product on account of trade conditions, or because the process is technically unsatisfactory. There may be developed, therefore, new methods or important modifications involving reconstruction or even new plants.

(b) Consideration of the manufacture of products not previously produced by the company is usually given as a result of market conditions or special wants of customers. Where a large consumption of a product of interest is developing, and the raw materials prove to be available, an investigation may be undertaken with a view to the selection of a process and the construction of a plant.

(c) The third source of investigation originates in the distinctly new processes so frequently offered to the world. Such processes, whether for a product manufactured by the company or of prospective interest, are always given the attention which their merits seem to warrant. No one who has a sensible process to offer is refused a hearing, and the treatment accorded the inventor soon becomes public opinion. As a rule, the inventor is retained to direct the development of his process under the management of the department.

As an investigation of a new manufacture includes a thorough examination of both the commercial and technical sides of the proposition, the commercial side, in which the assistance of the manager of the sales department and other commercial branches is invoked, calls for consideration of the following:—

(1) Its relation to the interests of the company; (2) the market; (3) manufacturing costs; (4) investment necessary; (5) source of raw materials; (6) transportation.

On the technical side a study must be made of:—

(1) The process; (2) other processes; (3) raw materials; (4) quality of product required.

These topics indicate the method of working out or testing the practicability of the process. This phase of the proposition is entirely a chemical and engineering one, and calls for most of the work of the investigation staff.

In the usual order of procedure, a proposal reaching the investigation department is subjected to a preliminary consideration, and is entered for record if it is to be made a subject for investigation. It is then submitted to the chemical council, which decides on the method of investigation to be pursued. A *résumé* of the literature is generally made and a report obtained from foreign representatives on the latest European developments. We may soon have to add the Japanese. As the inquiry progresses, the chemical council, which meets weekly, is kept informed of the progress made.

The thorough consideration given at this early stage frequently prevents useless laboratory expense and much loss of time.

Where an investigation of a process in use is being made, a member of the investigation department is sent to each of the works using it, to study the methods and management and analyse its defects. His reports thereon are considered by the chemical council in the manner indicated above.

If the final result of the investigation of a new process be favourable, an experimental plant may be recommended and an appropriation asked for. This may be advisable not only to assist in reaching a decision regarding the wisdom of adopting the process, but also for furnishing data for the designing of a manufacturing plant, if one be ultimately decided upon.

In the case of the adoption of a process and the designing of a plant, the work of the investigation and construction departments is very intimately connected. An investigation covers the inquiry regarding the proper design of the apparatus or plant, as well as the process *per se*

Investigations in connection with construction naturally differ, to a certain extent, and include consideration of methods for handling the raw material, the solids, liquids and gases involved in the process; furnacing, dissolving, filtering, evaporating, crystallising, distilling, subliming, drying, &c., and the packing and handling of the finished product.

The materials to be used in different parts of the construction are determined if an investigation into that important side be necessary, whether wood, cast iron, steel, lead, tin, aluminium, alloy, earthenware, porcelain, rubber, cement, &c. Any special data requested by the construction department in carrying out its work are furnished by the investigation department, such as the selection of fuel for special work, boiler and engine tests, consumption of steam, &c., and all chemical work.

The benefits resulting from organisation in the consideration of improvements and new processes are very evident. The results of experiments in one instance are applicable to others of distinctly different character. The full use of them demands a central bureau and clearing house of information.

The conferences held so frequently are not permitted to drag. Records are kept of all decisions, and even the local heads of departments present are notified in writing.

The routine work of the department consists in the collection and filing for easy access of technical and commercial data of all kinds connected with chemical manufacturing, for immediate and prospective use. Circulars containing useful information applicable to the works, and copies of research reports that may help operations, are transmitted to superintendents. Records of failure are just as important as those of success. Every encouragement is given superintendents to confer freely on any modifications, developments, or conceptions which may occur to them. The *esprit de corps* resulting naturally reaches the junior men and foremen, so that a keen sense of responsibility and importance is felt throughout.

The frequent visits of managers and superintendents to the head office, and the periodic meetings of superintendents which are called for conference and discussion enable the responsible men to continue in perfect familiarity with the technical resources of the company.

The research department would not be complete without a laboratory plant, large enough to work out processes on a small manufacturing scale. Such a plant should have all the standard appliances, and be so arranged that the results obtained in it are sufficient to form the basis for the engineering work resulting in the experimental plant to follow the successful investigation.

After all the organisation has been perfected and the machinery lubricated and put in motion, it would be apt to run wild if some trustworthy and absolute method of control should not be at hand. This I have found completely accomplished by a department which has to do with the compilation of facts and the deductions from them. It is absolutely essential, in a company operating a number of plants, that those in control should not only know what each one of its manufactured products costs, but what enters into making up that cost, so that if for any reason there is a drain going on it will be quickly known, located and stopped; or if, on the other hand, something advantageous shall have been accomplished, that will also be noted and imitated at other points. This may seem like an exceedingly difficult undertaking in an industry of such infinite variety, but a brief consideration will show that it is not so. The statistical department, to which I allude, is not only able to advise the officers within a reasonable time after the end of each month of the cost of every product and step, but also of the profit or loss on each article and the total profit or loss of the company. These results have been so exact that for several years the profits determined by public accountants at the end of the year have not varied 1 per cent. from those which had been worked up in this statistical department month by month. The importance of this information to those in control will be readily understood. For my own part, I do not see how it would be possible intelligently to run a large enterprise involving a number of plants without some such arrangement.

The exact plan which I would recommend is as follows:—

Each factory furnishes monthly the following reports:—raw materials received; raw materials used; shipments of finished products; stocks of raw materials; stocks of finished products. Productions and statement of statistical charges (including manufacturing labour, labour on repairs, material taken from the storehouse for repairs, all material taken from the storehouse for manufacturing except fuel and raw materials), packages, dry barrels, &c., included in the selling price and not returnable, manufacturing cartage (*i.e.* teams used around the works), steam and water.

The first shows the number of pounds of raw material received, together with cost of placing in the pile, and by adding the amount of bills, freight, &c., we get the actual cost per hundred pounds of each. These figures are used in obtaining the material cost of each hundred pounds of production, which, with sundries, labour, fuel, and repairs, makes up the total manufacturing cost, and in connection with that shows what each department has accomplished during the month.

As each of the factory sheets is checked and every pound of raw material and finished product accounted for, nothing escapes which should be considered in costs.

In addition to the manufacturing cost are shown the cost per 100lb. of special factory charges (including such accounts as docks, dredging, fire equipment, laboratory, lighting, roads, maintenance of yards, watchmen, gatemen, &c.), and cost per 100lb. of goods produced due to salaries of superintendents and chemists, based on proportion of labour of each department and the total manufacturing labour.

The factory shipment sheets are checked with the accounting department as well as repairs and net selling prices obtained, lighterage, cartage, allowances, estimated freights, &c., being deducted.

By using the manufacturing costs and the net selling prices, we arrive each month at the gross manufacturing profits, and deducting taxes, insurance, office, and other general expenses, the net results are obtained.

All organisation, whether in the chemical industry or any other, would fail to attain the best and most permanent results if the personal equation be forgotten. We are not dealing with a collection of apparatus, but with an organisation of men, everyone an individual, with his own peculiarities and ambitions. The day has not come, if it ever will, when from purely altruistic motives a man will give his most efficient services. He must realise that while his best work must be done, it will not go unnoticed and unrewarded. He must be sure that he will receive just and proportionately liberal treatment. His proper ambitions must not be smothered, they must be directed. From an experience of many years, I believe the plan outlined above provides fully for this most important fact, and I can point with the greatest pleasure to many men as proof of my statement, and every one more enthusiastic than at the beginning. The places of the leaders will someday be vacant. Who, then, shall fill them? Those whose lives have been spent in preparation for the work, and who will enter into it without shock or derangement of existing conditions, but as naturally as the stream flows into the river. Thus will the natural ambition of the young man reach its fulfilment in due time, and thus will our beloved industry progress to points of attainment which some of us may dream of, but will never see.

A vote of thanks to the president for his address was then proposed by Prof. Divers and seconded by Sir Henry Roscoe, the first president of the society, in the course of which allusion was made both to the valuable character of the address to which the members had just listened, to the origin of the society some twenty-five years ago, and to the considerable growth in its membership which the council's report indicated. In responding, Dr. Nichols spoke of the advantage which ensued to the society as a whole as a consequence of the visit last year to America, followed, as it happily had been, by the present visit to England of a considerable number of members from the other side of the Atlantic. He said how much he and his fellow-countrymen appreciated the hospitality that had been already shown them, and the efforts that had been made in connection with the interesting and lengthy programme that had been arranged largely for their benefit. He said that in New York they had been anxious to provide some souvenir of their visit that they might leave behind them, and, on informing the meeting of the report of the scrutineers, which declared that Prof. Divers, F.R.S., had been elected president for the ensuing year, he desired to place in his hands the little thing that they had ventured to have prepared. This was a presidential badge formed of a medallion of Sir Humphry Davy surrounded by an emblematical device representing the union of England and America in the pursuit of chemical science. He trusted that the council of the society would authorise the wearing of the badge by all his successors in the office of president, and hoped it would help still further to cement the good feeling and cordiality which existed between members of this great society on both sides of the Atlantic. He concluded by announcing the names of the vice-presidents and ordinary members of the council who had been found to be duly elected to office.

Prof. Divers expressed, on behalf of the society, appreciation of the kindness which had dictated the offer of this valuable presidential badge.

On the motion of Dr. Bailey, seconded by Mr. Hübner, who on behalf of Manchester promised a very hearty reception, it was resolved that the next annual general meeting should be held in that city.

On the motion of Prof. Chandler, of Colombia University, seconded by Sir Boverton Redwood, the hearty thanks of the society were accorded to the senate and council of University College for granting permission to the society to meet in that building. This was responded to by Sir William Ramsay, who incidentally referred to the fact that University College as a separate corporation had just ceased to exist, having become absorbed in and an essential part of the University of London. The meeting then adjourned.

THE UNIVERSITY OF SHEFFIELD.

As has already been noted in these columns, the new buildings of the University of Sheffield were on Wednesday of last week opened by the King and Queen, and by the act a new centre for research was created in this country.

Nothing seems to have been lacking to make the ceremony a success; all taking part, from the King downwards, entered into the proceedings with enthusiasm. In replying to the address of welcome presented by the city, the King said that he and the Queen were glad to be present to open the university buildings and to inaugurate a work which he was assured would tend to promote the

advancement of knowledge and the spread of culture among all classes in the city. He had no doubt that the establishment of the university would also afford facilities for the technical training which is now essential to success in every industrial enterprise, and concluded by saying that he should follow the progress of the university with warm interest. It may be mentioned here, as indicating His Majesty's interest in the spread of university teaching, that he has since sent through Lord Londonderry a letter to the Lord Mayor of Sheffield stating that "the opening of the new university buildings was felt by their Majesties to be an occasion of great importance. His Majesty has recognised with pleasure the desire felt in some of the great centres of industry and commerce that universities should take a prominent part in the promotion of scientific knowledge and research. . . . His Majesty recognises that in these days of constantly increased application of science and of scientific method to every department of modern life, it is to the universities that the nation must largely look for maintaining that position in relation to great commercial and industrial problems which is essential to the social well-being of his Empire."

His Majesty has also sent the following reply to the address presented to him by the university authorities:—"I view with lively satisfaction the establishment of this and other universities in large industrial centres, and it gives me great pleasure to open the handsome and spacious buildings provided for the University of Sheffield. I have never ceased to watch with great interest the great development of the wide movement for the encouragement of a sound and liberal education among all classes of my people, and I am well assured that the expectations of those patriotic and enlightened men by whose efforts were established the institutions from which the University of Sheffield derives its origin will be justified by the achievements of those who are educated within these walls."

The opening ceremony was preceded by the reading of the above-mentioned address from the University by the Chancellor—the Duke of Norfolk—from which we extract the following sentences:—"We bear in proud and grateful memory the fact that on more than one previous occasion members of your Royal House have shown an interest in the instructions from which the University of Sheffield derives its origin, and we gladly recall what has been already achieved in the course of your reign to advance that wider movement of which this university is but a sign and symbol. The early years of your Majesties' reign must always be remarkable as having witnessed that more general awakening on the part of your Majesties' subjects to the advantages of higher education in all branches of learning and that better understanding of its needs and requirements which is evidenced by the almost simultaneous creation of five independent universities, at Birmingham, Manchester, Liverpool, Leeds, and Sheffield. The distinction conferred upon the inauguration of our university by the gracious presence of your Majesties here to-day is of the happiest omen for its future, and we can only hope and pray that the teaching given within these buildings, the learning acquired within these walls, and the influences that will follow from them, may prove not unworthy of the great honour you have done us, and may be a constant source of profit and of ever-increasing usefulness to all classes of your Majesties' loyal and loving subjects within these districts."

The Duke of Norfolk then addressed the King, and in the course of his remarks, after paying tribute to the men to whom the university movement in Sheffield is mainly due, stated that it was now three years since it had been thought necessary to gather into one home the various sources of educational work which the university ought to supply; and the faculties of arts, of pure science, and of medicine have now been gathered together. Applied science is in another very adjacent building. He stated that every class in Sheffield has shown keen interest in the work, and that the sum of 20,000*l.* is needed to meet the expense of erecting and endowing the university.

Reference having been made to the granting in May last of the charter to the university, the King was handed a key and requested to declare the university open. This he did, speaking as follows:—"I have great pleasure in declaring these beautiful buildings open; and it is my fervent hope and desire for the long-continued prosperity of the University of Sheffield."

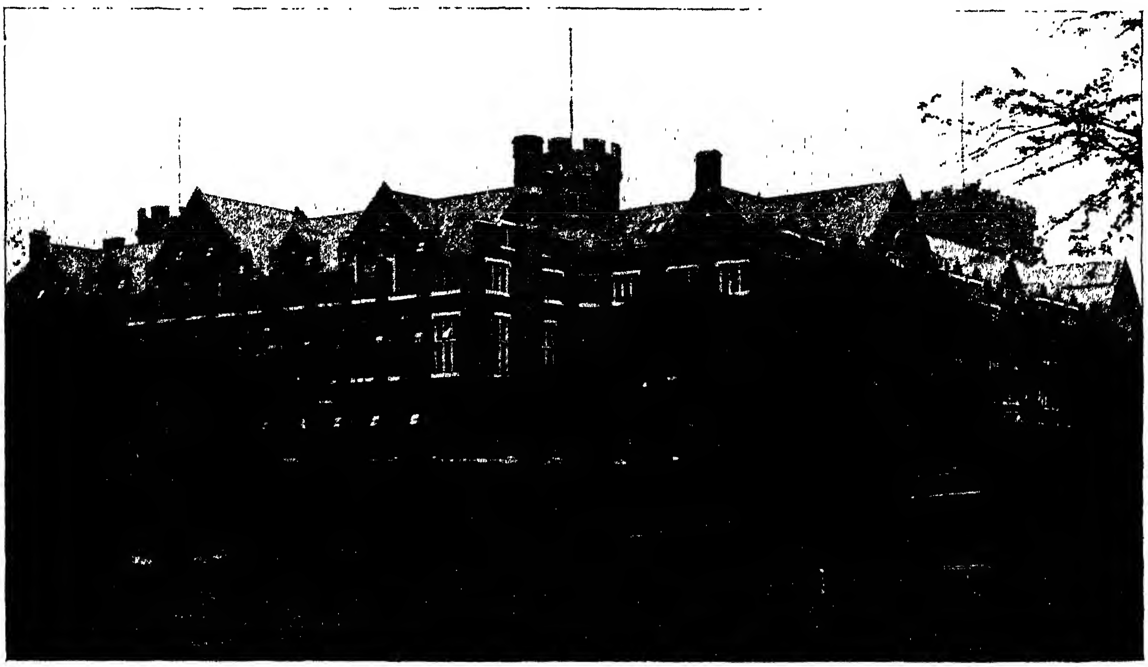


Photo. by Pawson and Brailsford, Sheffield.

FIG. 1.—The University Buildings from Weston Park.

The following is a short description of the new buildings. The illustration (which we are able to give by permission of Messrs. Pawson and Brailsford, of Sheffield) is a view of the university from Weston Park.

The buildings are constructed of red brick and stone in the Tudor style of architecture, form three sides of a quad-

rangle, and are situated upon a site overlooking Weston Park. A tower has been erected at one corner of the quadrangle, octagonal turrets at two of the other corners, the site of the third turret together with the fourth side of the quadrangle being left vacant in order to provide for future extensions. The building on the south side, which faces Western Bank, contains the large hall of the University; this hall is to be known by the name of the Firth Hall, after the founder of Firth College. The Firth Hall is designed to accommodate an audience of about 800 persons. In the same building are the administrative offices, the council room, the common rooms and refectories. The building on the west side provides for the departments in the faculties of arts and pure science, that on the north for the departments in the medical faculty. The faculty of applied science is located on a separate site about four minutes away in St. George's Square.

The physical laboratories contain a superficial area of 10,000 square feet, and are self-contained on three floors connected by a spiral staircase and apparatus lift, the rooms on each floor being arranged on either side of a central corridor except those on the lower ground floor, which, owing to the slope of the ground, are confined to the quadrangle front. Accommodation is provided for all the various departments of physics, except electrical engineering, which is housed in the buildings for applied science in St. George's Square.

The chemical department occupies the northern half of the top floor in the western block, and has a floor area, including corridors, of 7400 square feet. Two lecture theatres are provided. The larger, 30 feet by 40 feet, is furnished with seating accommodation for 110 students. A preparation room for lecture experiments adjoins this. On the other side of the corridor is a smaller lecture theatre to accommodate 34 students; this will be utilised for tutorial work, and for work with small classes.

There are laboratories for elementary and advanced students, and a small one for research work.

The biological department, which includes the two subjects of zoology and botany, adjoins the chemical department, and occupies the southern half of the top floor of the west wing. A lecture room is also allotted to this department on the first floor, and the whole of the upper part of the tower. There are two lecture rooms, the larger having accommodation for about 80 students. The general laboratory, with a raised platform and table for the purpose of practical demonstrations, and the botanical laboratory afford accommodation for 30 students each; there is also a zoological laboratory for advanced students, besides zoological and botanical research laboratories.

The anatomical department includes a large lecture theatre, a museum, several research laboratories, and private rooms for the professor and demonstrators. Accommodation for microscopes and stereoscopes is provided, also a set of the most modern anthropological instruments, and requisites for students who may desire to do work in modern developments of anatomy.

The physiological department has an area of about 5400 square feet. There are nine rooms in the department, and no corridors, the rooms opening into each other; the three largest of these are the general laboratory, 70 feet by 25 feet, the chemico-physiological laboratory, 50 feet by 25 feet, and the lecture theatre. Another large room in the department is the general research room, 25 feet by 30 feet. The rooms in this department, like all the other rooms on the north front, are lighted with specially large windows in order to facilitate microscopical work, and have several concealed sinks in the floor, which, when opened, reveal supplies of gas, water, and electricity, thus avoiding the necessity of fixed benches, their place being taken by movable tables.

The pathological department occupies the whole of the upper floor of the medical block; the main feature is the large students' laboratory facing north, 70 feet by 26 feet, divided by two partitions. There are adjoining this two laboratories, one large and one small, intended for the bacteriological work to be done in connection with the City Health Department. A special feature consists of an incubating room in the centre of the department, so arranged that it can be kept at a constant temperature; this room will replace the ordinary incubating ovens. There is a large lecture theatre in the department, a museum with a top and a south light, a special research laboratory, also private rooms, photographic and store rooms—the last two mentioned being in the roof and the turrets above the department.

The new buildings allotted to the engineering department consist of four floors; the lowest floor or basement contains a large extension of the original laboratories. The main engineering laboratory contains a plant which can be used both by mechanical and electrical engineering students. There is also a very complete electrical equipment in the new building to demonstrate the applications of electricity to lighting, traction, and power transmission.

The department of metallurgy has had special attention paid to it, seated as it is in a city where the chief national metallurgical industry is carried on. As a natural consequence of this, so far as iron and steel metallurgy is concerned, the metallurgical laboratories of the University of Sheffield are unique. These laboratories are divided into two sections, the scientific and the practical. In the first named there are nine, and in the second two laboratories.

GEOLOGICAL NOTES.

AMONG recent publications of the Geologische Reichsanstalt of Vienna, Herr G. Geyer (*Verhandlungen*, 1904, p. 363) discusses the nature of the pre-Jurassic floor of Austria, from a study of blocks of crystalline rock embedded in Liassic sandstone, and of the island-like "Klippe," formed of granite, which lies N.W. of Weyer, and which has been utilised for the memorial of von Buch. This mass of granite, by-the-by (Toula, *ibid.*, 1905, p. 89), was correctly appreciated as a projecting mass of older land, and not as an erratic block, by von Hochstetter as far back as 1869. Herr Geyer refers to many instances of "exotic blocks" north of the Alps, and points out the influence of the old gneissic and granitic foundation on the subsequent folding in the region of the Enns. Herr R. J. Schubert (*ibid.*, 1904, p. 461) adds greatly to our knowledge of the Upper Eocene and Oligocene beds of Dalmatia, while Dr. Franz Kossmat (*ibid.*, 1905, p. 71) shows how the Sava began to flow eastward on the uplifted floor of a Miocene gulf, and formed the plain near Laibach by filling in a depression that developed during the latest movements of the Alps. In the department of palæontology, Dr. Katzer (*ibid.*, 1905, p. 45) furnishes an interesting account of the microscopic structure of the Devonian Tentaculite-limestones of Bohemia, which may be regarded as a valuable supplement to Novák's work on Tentaculites (*Beiträge zur Pal. Oesterreich-Ungarns*, ii. Bd., 1882). Herr Theodor Fuchs (*Jahrbuch der k.k. Reichsanstalt*, 1904, p. 359) reviews in considerable detail a number of recent papers on fucoids, and concludes that these problematic organisms were not washed into the strata after the manner of floating seaweeds, but arose where they are now found. He insists that museum-specimens in such cases are likely to be misleading, and that a study of fucoids in the field shows that some, at any rate, run perpendicularly to the strata by which they are surrounded. Herr G. Stache (*Verhandlungen*, 1905, p. 100) again investigates the globular Cretaceous organism named by him Bradya, and gives it new interest by showing its resemblance, in structure and mode of occurrence, to Brady's recent genus Keramosphæra, described in 1882 from the deep sea south of Australia. Bradya has long been connected with Steinmann's hydrozoan form Porosphæra; but Stache is now able to revive it, and once more to refer it to the foraminifera. Students of our well known British form Parkeria will find much to interest them in this paper. Herren Hofmann and Zdarsky (*Jahrbuch*, 1904, p. 577) discuss and illustrate the dentition of Deinotherium, and the abundant remains of a species of antelope, from the Miocene beds of Leoben.

The *Transactions of the Geological Society of South Africa* for January to April contain several stratigraphical and structural papers by Dr. Molengraaff and others; but general interest will be raised by the illustrated description of the great Cullinan diamond, by Messrs. Hatch and Corstorphine, on p. 26. In the *Transactions of the South African Philosophical Society*, vol. xvi. (1905), Mr. Rogers

(p. 1) confirms his discovery of a glacial conglomerate, the Pakhuis bed, in the Table Mountain series near Clanwilliam. A thousand feet of sandstones, probably fluviatile, overlies these glacial strata, and the Devonian Bokkeveld beds follow, so that the antiquity of the conglomerate, as compared with the well known Dwyka beds, is put beyond a doubt. Mr. Schwarz (*ibid.*, p. 9) makes a block of gneiss from the volcano of Tristan d'Acunha serve as the text for a dissertation on oceanic islands in general, which he expands further into a treatise on several points in theoretical geology. We confess to a feeling of nightmare, as the one innocent specimen leads us on into enormous fields of speculation, where a considerable area is occupied by the slaying of the slain. When, after twenty-six pages, we reach the question, "What, after all, are volcanoes?" we are tempted to turn over the next eight, to where the description of "the rocks of Tristan d'Acunha" nestles humbly as an appendix. Mr. A. L. du Toit (p. 53) furnishes a serious paper on the forming of the Drakensberg, which summarises many recent observations. Stress is laid on the numerous volcanic necks and lava-flows, which are later than the Cave Sandstone. In some cases, the vents contain no igneous matter, but merely masses of exploded sandstone and shale, in a ground of pulverised grit. Dr. R. Broom re-opens (*ibid.*, p. 73) the whole question of the age and affinities of Tritylodon. Those who were present at the memorable meeting in London in 1884, when Owen laid upon the table what was believed to be the oldest known mammalian skull, will read with some surprise of the doubt which hangs over the locality and horizon of the fossil. Dr. Broom believes that it came, as then stated, from Basutoland; if so, it is from the Stormberg beds, which he regards as of Lower Jurassic age. As was pointed out in NATURE, vol. lxxii. p. 36, the reference of the reptilian beds of South Africa to the Permian may carry back the Stormberg beds also, and this will make Dr. Broom's defence of Tritylodon as a mammal, and not a reptile, of even greater interest as research goes on.

Dr. A. E. Salter (*Proceedings of the Geologists' Association*, vol. xix. p. 1) produces a large amount of original evidence bearing on the sources of the superficial deposits found above the Jurassic and Cretaceous strata to the south, north-west, and west of London. The area studied is a wide one, and Dr. Salter traces fluviatile action in it to an epoch before the deposition of the "Boulder-clay." Among his interesting conclusions, we note that a large amount of "drift" material in the lower basin of the Thames is of southern origin, suggesting that "the southern slope was formerly more extensive than at present," the distribution of such material having been probably aided by earth-movements. In support of this latter contention, it is shown that Lower Greensand chert from the Wealden area occurs 650 feet above the sea at Goring Gap. The Lower Thames Valley is thus held to be of recent geological age (pp. 17, 25, &c.). Other evidence is adduced of the modification of the general direction of drainage by earth-movements since the higher gravels were deposited.

Dr. O. Mann begins, in the *Sitzungsberichte der Gesellschaft Isis* (1904, p. 61), what promises to be a detailed account of the tin-deposits of the Erzgebirge, including a microscopic examination of the veins of quartz, tourmaline, and cassiterite.

Dr. J. W. Spencer further emphasises his views as to submerged river-channels and continental shelves in two notices of the work of Hull and Nansen (*American Geologist*, vol. xxxv. pp. 152 and 222). He provides us also with a useful bibliography of the subject in relation to America (*American Journal of Science*, vol. xix. p. 341).

A preliminary note on the geology of the provinces of Tsang and Ü in Tibet, by H. H. Hayden (*Records, Geol. Survey of India*, vol. xxxii. p. 160), forms a pleasant outcome of the recent political expedition. Marine Cainozoic beds are found north of the Sikkim border, and there is evidence of a former considerable extension of glaciers northward from the Himalayas. The granite near Lhasa is intrusive in a wide area of Jurassic strata, which have suffered much from crushing and metamorphism. The country does not appear rich in minerals, and even the gems are imported.

G. A. J. C.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Amongst the list of donations to the university benefaction fund which was recently published by the Vice-Chancellor the following sums may be mentioned:—the Right Hon. Lord Rayleigh, 5000*l.*; the Right Hon. Lord Iveagh (further donation), 1000*l.*; C. J. Heywood, Esq., 100*l.*; J. Lumb, Esq., 100*l.* Besides these a number of smaller sums have been received, some of which are especially allocated to the Huddersfield lectureship in pathology. In addition to these sums the Cambridge University Association has collected more than 6000*l.* towards the fund for the university library. The success of this is due almost entirely to the energy of the registrary. The Schuter scholarship in St. Bartholomew's Hospital has been awarded to Mr. R. B. S. Sewell, late scholar of Christ's College.

DR. T. G. PINCHES has been invited to join the staff of the institute of archæology of the University of Liverpool as assyriologist.

THE resignation of Mr. H. J. L. Beadnell from his position on the Geological Survey of Egypt is announced. Mr. Beadnell has been connected with the survey since 1896, *i.e.* from the time it was established.

FROM a long list of recent changes we extract the following appointments to professorships at technical colleges:—Prof. M. Disteli at Dresden, for descriptive geometry; Mr. Camillo Körner and Prof. K. Zsigmondy at Prague, for machine construction and mathematics respectively; Dr. Leo Grünmach at Berlin; Dr. Gustav Rasch at Aachen; Dr. Clarence Feldmann at Delft, for electrotechnics; Dr. A. Tobler at Zurich, for applied electricity; Prof. F. Schilling at Charlottenburg, for geometry. W. König, of Greifswald, has been appointed professor of physics at the University of Giessen, and Dr. Karl Stöchl professor of mathematics and physics at Passau.

THE proposal made by the Emperor of Germany for the temporary interchange of professors with America for a course of lectures is leading to a number of important results. Harvard University has invited Prof. Ostwald, of Leipzig, to give a half year's course, Columbia University has secured lectures from Prof. V. F. Bjerknes, of Stockholm, on "Fields of Force," and from Prof. H. A. Lorentz, of Leyden, on "Extensions of Maxwell's Electromagnetic Theory." Is Great Britain with its usual insularity going to keep aloof from the new movement? It is hardly likely that any proposal from our country would fail to obtain hearty support either in Germany or in America.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 9.—"The Rate of Transmission of the Guatemala Earthquake of April 19, 1902." By R. D. **Oldham.**

This paper contains a complete study of an earthquake from the point of view of the rate of transmission. The time and place of origin are known with a sufficient degree of accuracy, and the shock was of sufficient power to give distinct records even at 160° from the origin. Three phases of wave motion are recognised, the third phase including all those which are distinguished in Japan by the symbols P_3 . . . P_8, as the author believes that it is doubtful whether there is any real difference in the character of the wave motion, or whether, in these so-called phases, we have not waves of essentially similar nature, but varying rates of propagation. The first and second phases are, however, of distinct character, being mass-waves, differing from each other not only in rate of propagation but in character of wave motion. Of these, the first phase shows a continuous increase in the apparent rate of propagation as the distance from the origin becomes greater, and seems to emerge almost simultaneously at all points more than 145° from the origin. The second phase shows an increase in the apparent rate of propagation up to 100°, and a decrease beyond this; the result is unexpected, but the author, while remarking that it must not be rejected on that

account, also points out that the second phase is much less well marked in the distant records than in the nearer ones. From the figures given in the paper, it appears that the times taken by the three phases of wave motion to travel from their origin to its antipodes are respectively about 20, 50, and 100 minutes.

Physical Society, June 30.—Dr. R. T. Glazebrook, F.R.S., past-president, in the chair.—The comparison of electric fields by means of an oscillating electric needle: D. **Owen.** This paper describes experiments which show how an "electric needle" may be used to measure electric fields in a manner similar to that in which a magnetic field is measured by an oscillating magnetic needle. The needles used were cylindrical in form, of aluminium or of brass, and were suspended by quartz fibres three or four inches in length. The couple on the needle when disturbed from the direction of the field is proportional to the square of the field strength. For small displacements the needle vibrates isochronously, the frequency being proportional to the electric force. It may be used in alternating as well as in steady fields, and may be applied to illustrate many of the laws of electrostatics. The disturbing effect of the needle upon the field is considered; in particular its effect when placed in a uniform field. It is shown by experiments that the disturbing effect falls off rapidly with the distance from the needle, and is inappreciable (in the case of a needle 1½ cm. long) at a distance of twice the length of the needle. With regard to the effect of the dimensions of the needle upon the frequency (for given field), while the restoring couple decreases rapidly with decrease of size, yet the moment of inertia decreases more rapidly, so that the smaller the needle the greater the frequency, and also the smaller the disturbing effect. The shielding effect of some dielectric materials was examined in the following way:—A needle was suspended centrally in the uniform field between a pair of parallel plates. A thin-walled cylinder of the dielectric was placed around the needle, and the shielding action denoted by a fall in frequency of the needle. Glass and mica were found to effect perfect shielding. Ordinary paper shields; but when thoroughly dried by heat the electric field is transmitted undiminished only to fall off to zero after a minute or two's exposure to the air. Dry paper soaked in melted paraffin-wax transmits the field perfectly and for an indefinite time. The paper concludes by pointing out that an electric needle suspended between a pair of parallel plates forms a simple means of measuring high voltages, since the frequency of vibration is simply proportional to the voltage between the plates.—The magneto-optics of sodium vapour and the rotatory dispersion formula: Prof. R. W. **Wood.** It has been shown in a previous paper that the vapour of metallic sodium is an ideal substance for investigating the effect of a strong absorption band on the magnetic rotation of the plane of polarisation. The preliminary work was not very satisfactory, as the method employed did not admit of very accurate determinations of the wave-lengths. Improvements in the methods of observation and design of the apparatus have been accompanied by an increase in accuracy, and accurate readings have been obtained for as many as nine different values of λ between D_1 and D_2. Rotations as great is 1440° (four complete revolutions) have actually been observed, and this with a 10 cm. column of not very dense vapour in a field of 2000 C.G.S. units. In the present paper the magneto-optics of the vapour for light travelling along the lines of force are discussed. The sodium was heated in a tube of thin steel, the ends of which projected from the helices of the magnet. It was found that the field strength within the steel tube did not differ greatly from that obtained when glass tubes were used. A short piece of small brass tubing is brazed into one end of the steel tube, through which the steel tube is exhausted. A good vacuum is essential, all traces of rotation disappearing in hydrogen or nitrogen at atmospheric pressure. Light from an arc-lamp made parallel by a lens is passed through a Nicol's prism, the steel tube, and a second Nicol, after which it is brought to a focus upon the slit of a spectroscope by means of a second lens. In the present case, a concave grating of 14 feet radius was used instead of a spectroscope, the observations being made both visually and by means of photography. The paper then describes the phenomena which are presented when the sodium vapour is formed in the magnetic field. In the case of very dense vapours the rotation has been measured over a considerable range of wave-lengths, namely, throughout the region comprised between $\lambda=5840$ and $\lambda=5922$. The rotation constant of D_2 was found to be about double that of D_1. Drude, in his "Lehrbuch der Optik," has given two formulæ for the magnetic rotatory dispersion, the first of which, developed from the hypothesis of molecular currents, calls for an anomalous effect on crossing the band, and does not apply to sodium vapour. The second, developed from the Hall-effect hypothesis, predicts rotations of similar sign and equal magnitude for wave-lengths symmetrically situated in the spectrum, with respect to the centre of the absorption-band. It seems likely that the molecular currents play some part, and that the formula built up on the hypothesis of the Hall-effect is incomplete. However, the latter formula represents the rotation outside of the D-lines with great accuracy, while between the lines it gives in some cases a curve which is elevated somewhat above the experimental curve. The paper concludes with an account of the bright-line spectrum produced by magnetic rotation which presents itself when the Nicol's prisms of the apparatus are crossed. The spectrum, which at first could only be seen with difficulty, was finally obtained of such brilliancy that it could be photographed with a 14-feet concave grating. A good vacuum was found to be an essential condition, the presence of inert gases causing a faintness of the lines.—The fluorescence of sodium vapour: Prof. R. W. **Wood.** The fluorescence of sodium vapour has been investigated by allowing light of various wave-lengths to illuminate the vapour, and then studying the light emitted with a spectroscope. Approximately homogeneous light of any desired wave-length is obtained by means of a monochromatic illuminator. Some sodium is placed in a horizontal steel tube fitted with steel ends, in one of which is a circular aperture bored just above the centre. The tube is heated and the vapour rises until it reaches the hole. The light from the monochromatic illuminator passes through the hole and falls upon the vapour. The fluorescent light is then observed by means of a spectroscope either visually or by photography. It is essential that the incident light should not traverse an appreciable amount of the vapour, or the fluorescent effects are masked by those of absorption. The bright lines of the fluorescent spectrum are by no means the exact complement of the absorption spectrum. Very remarkable effects have been observed when the vapour is illuminated with a *very* narrow band of approximately homogeneous light, the lines in the fluorescent spectrum changing their position and appearing to dance about with the slightest change in the wave-length of the exciting light. The motion is of course only an illusion, lines disappearing and others re-appearing, like the sparks of a spinthariscope. Stokes's law is violated in a most flagrant manner, bright lines coming out on both sides of the excited region. The behaviour of the spectrum indicates that we are dealing with a number of groups of electrons, each group containing a large number of vibrators. The excitation of one of these vibrators sets the whole group going, but does not start disturbances in the other groups.

EDINBURGH.

Royal Society, June 19.—Dr R. H. Traquair in the chair.—A comparative study of the dominant phanerogamic and higher cryptogamic flora of aquatic habit: George **West.** The paper referred to three loch areas of Scotland, namely, Loch Ness, the district between Nairn and Forres, and the Island of Lismore. In the first district the waters were peaty, in the third they were heavily charged with lime and were free of peat, while in the second district the waters were neither limey nor peaty, but were turbid and unwholesome in appearance, due to the presence of marsh gas. These characteristics influenced in a marked degree the habit of the aquatic flora, the distribution and growth of which were also dependent on the direction of the prevailing winds. Interesting details were given.—Les concrétions phosphatées de l'Agulhas Bank (Cape of Good Hope): Dr. Léon W. **Collet**; avec

une description de la glauconie qu'elles renferment, par Gabriel W. **Lee.** The work was undertaken under the direction of Sir John Murray, whose large collection of phosphatic nodules had been greatly enriched by the concretions dredged off the Cape of Good Hope by the steamer of the Department of Agriculture, and presented by Dr. Gilchrist, the Government biologist. The concretions were found beyond the 100-fathom line down to depths of 800 fathoms. Their occurrence, as already pointed out by Sir John Murray, is closely connected with the oceanographical question of the variability of temperature in certain regions. The mingling of two currents of different temperature is necessarily attended by a great mortality among the creatures living in these waters, and their dead bodies falling to the bottom produce ammonia and phosphate of lime. There can be little doubt that the glauconite and phosphates found in geological strata have been formed under similar conditions. In the material from the Agulhas Bank two kinds of nodules were found :—(1) those with Foraminifera and other calcareous organisms ; (2) those without carbonate of lime and with the glauconite grains cemented together by phosphatic matter. These implied different modes of formation. Mr. Lee recognised two kinds of glauconite in the phosphatic nodules, the occurrence in the one kind being in the form of grains with definite contours, in the other in the form of a diffused pigment.—Note on some of the magnetic properties of demagnetised and annealed iron : James **Russell.** The iron was demagnetised by one of three methods, namely, by decreasing reversals of magnetic force co-directional with the field to be afterwards applied in the study of the permeability, by decreasing reversals of a transverse force, or by annealing. The permeabilities after these processes of demagnetisation were carried out were then compared, and various interesting conclusions arrived at. One very remarkable result was that, however much the values of the permeability differed under these varied conditions, the value of the coercive force (as defined by Hopkinson) was almost exactly the same in all cases.—Certain mathematical instruments for graphically indicating the direction of refracted and reflected light rays : J. R. **Milne.** These simple devices were not only useful in demonstrating the course of reflected and refracted rays, but could also be effectively used in graphically solving problems in geometrical optics the algebraic solution of which presented insurmountable difficulties in the way of carrying out the necessary eliminations.—On the hydrodynamical theory of seiches : Prof. **Chrystal.** This paper contained the mathematical solution of problems suggested by the phenomena of seiches in lakes, and showed how the periods of the various possible seiches and the positions of the nodes were affected by the contour of the lake bottom.—On a group of linear differential equations of the second order, including Chrystal's seiche-equations as special cases : Dr. **Halm.** This formed an important sequel to the foregoing paper, giving a mode of arriving at a solution of a case in which the direct method led to a slowly converging series, ill-suited for numerical determinations.—A monograph on the general morphology of the myxinoid fishes, based on a study of myzine, part. i., the anatomy of the skeleton : Frank J. **Cole.** By controlling the dissections by charts reconstructed from serial sections, the author obtained many results of importance in working out the micro-anatomy of the skeleton. Previous descriptions have thus been much extended, and the phylogenetic origin of the myxinoid skeleton may now be shown to be much simpler than has been hitherto supposed.

July 3.—Prof. Geikie in the chair.—The plant remains in the Scottish peat mosses, part i. : Francis J. **Lewis.** The paper contained a detailed account of the botanical stratification of peat mosses in the Scottish southern uplands, the discussion being in every case based upon evidence derived from freshly cut holes or from borings. The geological horizons were determined in most cases by the fact that the mosses rested on moraines which were known to belong to one of the Glacial periods. The conclusions were in full accord with the views originally put forward by Prof. James Geikie, and demonstrated the existence of the third, fourth, and fifth periods of glaciation in Scotland, those, namely, which are distinguished as (3) the district ice sheets, (4) the mountain valley glaciers, (5) the corrie glaciers.—Dissociation of the action of the auricles and ventricles : Dr. W. T. **Ritchie.** The paper contained an account of curious cases of heart block, a subject first studied scientifically by Gaskell. The graphs of the various pulse rhythms were obtained side by side, enabling the eye at a glance to contrast them and so prove the absolute independence of the action of the auricles and ventricles.—Cape hunting dogs (*Lycaon pictus*) in the gardens of the Royal Zoological Society of Ireland : Prof. D. J. **Cunningham.** The chief interest attached to these dogs was that they had been for the first time reared in captivity. The parents had been got from Holland, and during the four years 1896 to 1900 there had been four litters, but only three of the puppies had been brought to maturity. The peculiar colouring of the adult dog with its yellow and white patches was absent in the puppy stage, but gradually appeared as the animal grew older ; also the dark band down the forehead became more marked with age. The animals were very intractable in captivity. An attempt to obtain a cross with a collie failed, the collie when introduced into the cage showing symptoms of excessive fear, while the male Lycaon paid not the least attention to her. The period of gestation in the case of the Cape hunting dog was found to be eighty days, somewhat longer than in the case of the domestic dog.—The Alcyonarians of the Scottish National Antarctic Expedition : Prof. J. A. **Thomson** and James **Ritchie.** The collection contained six new species, and specimens of three forms previously obtained by the *Challenger*. These were found in various latitudes, the furthest south specimen having been obtained in S. lat. 74°, off Coats Land. Our knowledge of the geographical distribution has been thus much extended. Of the beautiful *Umbellula durissima* the *Challenger* obtained one young specimen from the south of Yedo, while Mr. Bruce was fortunate in obtaining about a score of specimens, some of which are larger, older, and of more vigorous growth than that which Kölliker described in the *Challenger* reports.—The theory of determinants in the historical order of development up to 1852 : Dr. Thomas **Muir.**—On the action of radium bromide on the electromotive phenomena of the eyeball of the frog : Prof. **McKendrick** and Dr. W. **Colquhoun.** It has been known since 1871 that when the fresh excised eye of a frog is connected by unpolarisable electrodes with a sensitive galvanometer an electric current may be detected, and that definite variations take place in that current when the retina is exposed to the action of light. It is also well known that salts of radium are luminous in the dark, and that when a tube containing radium is pressed against the closed lid of the eyeball a luminous effect is produced. It was of interest to ascertain whether this luminosity was due to the radium causing fluorescence of any of the structures of the eyeball, or whether it was due to the direct action of the radium emanations on the retina itself. The radium employed was kindly lent by Dr. Hardy, of Cambridge. The conclusions were as follows :—(1) The light emanating from radium bromide affects the electromotive phenomena of the living retina of the frog in a manner similar to that of light, although to a considerably less degree ; (2) its action is not due to fluorescence of any of the structures of the eyeball, but to direct action on the retina ; (3) the retina of the frog will respond to emanations of radium passing through cardboard, blackened paper, thin glass, and aluminium foil, emanations which, when allowed to fall on the human eye in a perfectly dark chamber, do not give rise to a luminous sensation ; (4) the frog's eye is sensitive to the feeble light emitted from the surface of fluorescible minerals and fluids rendered fluorescent by radium ; (5) the β rays are responsible for most of the effects observed, but after they have been largely excluded by thick glass a slight effect still persists, due presumably to the γ rays ; (6) monochromatic light employed in a photographic chamber may still affect the electromotive phenomena of the living retina of the frog ; (7) no satisfactory evidence could be obtained of the action of the ultra-violet rays of a lamp filtered through a Wood's screen. The slight movement of the galvanometer observed with light "off" might possibly be ac-

counted for by mechanical disturbance of the apparatus. As already pointed out by Prof. Gotch, there is great advantage in "adapting" the eye to darkness or to coloured light for three or four days.

DUBLIN.

Royal Dublin Society, June 20.—Prof. W. Noel Hartley, F.R.S., in the chair.—On the supply of water to leaves on a dead branch: Prof. H. H. **Dixon.** The fading of leaves on a branch killed by the application of heat is shown experimentally to be due in many cases at least to the introduction into the transpiration current of substances which cause a loss of turgescence of the leaf cells; consequently this fading does not prove that the water supply in these cases is inadequate, but rather that it is contaminated. A diminution, however, of the water supply may be caused by the high temperature, if this latter determines the rupture of the water columns of the tensile transpiration current or brings about the exudation of clogging substances into the conducting tracts from the dying cells. The conclusion, based on the withering of leaves on a killed branch, that the intervention of living cells is necessary to the elevation of the sap is thus rendered superfluous.—On the diagnosis of the eye by means of pinhole-vision: Prof. W. F. **Barrett,** F.R.S. The self-examination of the eye by looking through a pinhole in an opaque screen was termed *entoptic diagnosis* by Listing, who submitted this method to careful examination more than fifty years ago. The author was independently led to a similar discovery by noticing fixed shadows on his own retina when a bright spot of light was looked at. These shadows proved to be due to cataract, and led the author to the construction of an instrument which he calls an *entoptoscope,* whereby the patient can easily draw the exact extent of the obscuration in either eye. By means of two closely adjacent pinholes in a revolving diaphragm in the eye-piece and a transparent scale, the actual magnitude and position of the opacity in the eyeball can be accurately determined.—On secondary radiation (part iii.): Prof. J. A. **McClelland.** A continuation of the author's researches.

PARIS.

Academy of Sciences, July 10.—M. Troost in the chair.—On a calculation of the elastic resistance offered by a tube without longitudinal tension to inflation by a contained liquid column: J. **Boussinesq.**—On some experiments relating to the radio-activity induced by uranium: Henri **Becquerel.** This paper contains a study of the properties of the body formerly discovered by precipitation from the mixed barium and uranium chlorides by sulphuric acid, and since probably identified with Crookes's uranium X. It shows a remarkable stability of activity at very high temperatures.—On the treatment of trypanosomatous disease (surra, mbori) by arsenious acid and trypan red: A. **Laveran.** Extending his investigations on this method of treatment, the author has definitely cured the disease in dogs, animals in which it has always previously proved fatal. No trace of infection could even be found in the blood of the cured dogs.—On the treatment of bone fractures by movement: J. **Lucas-Championnière.** This new method follows a law which surgery hitherto has ignored, that, in spite of their rigidity, bones, like other tissues, require movement to ensure the vitality necessary for recuperation. The practice which the author follows is a peculiar form of massage, and not only conduces to the formation of the hard tissue, but is also favourable to the quick reparation of other neighbouring organs, such as muscles and tendons, involved in the fracture.—On the use of rockets against hail: E. **Vidal.** This paper explains how they are effectual in those cases where the storm centre is at a low altitude.—Researches on algebraic integrals in the motion of a solid heavy body about a fixed point: Édouard **Husson.**—On a new preparation of rubidium and cæsium: L. **Hackspill.** The author finds that these metals can be obtained by a method similar to that for obtaining potassium or sodium, viz. by reduction at a dull red heat of the alkaline chlorides with calcium. The resulting metal does not even attack glass.—A comparison of properties, tests, and classification of ternary steels: Léon **Guillet.**—On the molecular transformations of hydrated ferric sulphate: A. **Recoura.** If a concentrated solution of ferric sulphate be allowed to stand for some days a deposit forms, which rapidly grows until the liquid becomes practically solid. This occurs through the formation of a mixture of basic sulphate and free acid.—On dextro-dilactide: E. **Jungfleisch** and M. **Godchot.**—On the hydrogenation of the ketoximes. A synthesis of new amines: A. **Mailhe.** Among others, acetoxime by reduction with finely divided nickel gives a mixture of isopropylamine and di-isopropylamine.—On the synthesis of a new leucine: L. **Bouveault** and René **Locquin.** This body is probably one of the four possible amino-butyl-acetic acids.—On sparteine, and the symmetric character of the molecule: Charles **Moureu** and Amand **Valeur.**—On a sulphate of chromium which resists the action of reagents: Albert **Colson.**—On the figures formed by pressure or percussion on plastic crystalline metals: F. **Osmond** and G. **Cartaud.** These consist of groups of lines, curved on iron, straight on other plastic metals of the cubic system.—On some points in the morphology of the schizopods: H. **Coutière.**—On the segmentary organs at the moment of sexual maturity among the Hésionians and the Lycoridians: Louis **Fage.**—On the retraction of the mouth in the Chetopods: C. **Viguier.**—On an estimation of the red corpuscles in human blood made at the summit of Mont Blanc: Raoul **Bayeux.** After giving a table of results, the author concludes that a rapid increase in the number of red corpuscles takes place with increasing altitude. This number soon falls off with some rapidity, but remains abnormally high even some time after a return to the lowest point.—On intestinal poisons (their nature, and precautions to be taken against them): MM. **Charrin** and **Le Play.**—On the preparation and properties of protoplasmic extracts from blood corpuscles: Auguste **Lumière,** L. **Lumière,** and J. **Chevrotier.**—On the activity brought about in pure pancreatic juice by the combined influence of colloids and electrolytes: Larguier **des Bancels.** An inactive pancreatic juice becomes under these conditions capable of digesting albumin.—On the decomposition of albuminoids by Actinomyces: E. **Macé.**—On the Tertiary beds of Ouennougha and Medjana (Algeria): E. **Ficheur** and J. **Savornin.**

THURSDAY, JULY 27, 1905.

THE AGENTS OF EARTH SCULPTURE.

Geology—Processes and their Results. By Thomas C. Chamberlin and Rollin D. Salisbury. Pp. xix+654. (London: John Murray, 1905.) Price 21s. net.

It is appropriate that this work is written by experienced members of the United States Geological Survey who are likewise heads respectively of the departments of geology and geography in the University of Chicago. The main portion of the volume treats of the earth's physical features and their origin, and thus illustrates the forces and processes which belong to the borderland between past and present in which geologists and geographers are alike concerned. No aspect of geology appeals to a larger circle of interested students and general readers. The preface being dated from the University of Chicago, it may be inferred that the book is published simultaneously in the United States. It is printed in bold type on thick paper, and with such abundant illustrations that it is a veritable picture-book. There are 24 plates and 471 text illustrations; the latter are not listed, however, in the table of contents. In the eyes of a book-lover the appearance of the book is somewhat marred by its being cut down rather too closely; but as the student will pay more attention to the subject-matter he may at once be assured that it is a sound, vigorously written work, abounding in original information and suggestions, and abreast of the ever-expanding knowledge to which American geologists have so largely contributed. Nor is there wanting due acknowledgment of many facts and illustrations drawn from published sources.

In their preliminary remarks the authors make a noteworthy use of statistics. Thus we read that "The total mass of the atmosphere is estimated at five quadrillion tons," that "About 1300 quadrillion tons of water lie upon the surface of the solid earth," and that the volume of the stony portion is about 260,000 million cubic miles. These estimates, incomprehensible by themselves, are rendered useful by comparisons, and the relative mass and extent of atmosphere, hydrosphere, and lithosphere are thereby brought clearly before the reader. It is pointed out that the oceanic depressions rather than the continental masses are the master phenomena of the earth's surface, and that if the surface were graded to a common level by cutting away the land and dumping the matter in the abysmal basins, the average plane would lie somewhere near 9000 feet below sea-level.

In dealing with the atmosphere as a geological agent, dust and blown sand, wind-ripples and wind-erosion, the influence of the colour of rocks on their daily range of temperature, the creep of soils and subsoils, and even the effects of lightning receive attention.

Rain and river erosion are discussed from hypothetical, and more fully from actual, points of view. Various stages in the history of streams and valleys are illustrated, and their distinguishing features in youth, in mature and in old age are described. It is pointed out that the base-level of erosion and sea-level are by no means synonymous, as rivers often erode below sea-level. The development of rivers under different structural conditions is explained, and attention is directed even to the possible influence of the rotation of the earth on the erosive action of streams. The beheading of one stream by another is treated as "piracy," and both "foreign" and "domestic piracy" are explained, the latter phrase being applied to cutting off an ox-bow in a meandering stream. Other terms of a somewhat homely nature are used, such as "scour and fill," in illustration of the fact that a stream in flood degrades its channel and aggrades (builds up) its plain.

There is a notable chapter on ground-water, a subject of great scientific interest as well as practical importance. The movements of ground-water include the fluctuations in its upper surface or "water table," and those dependent on the outflow of water in springs or on its abstraction by pumping, influenced as the movements also are by geological structure.

The work of snow and ice, of continental and alpine glaciers, is treated in an attractive and luminous style. The way of "getting load," the englacial and superglacial drift, the transfers of load from basal to higher portions of the ice, and the movements accompanied by shearing-planes and thrusts, are duly described.

"Hanging valleys" receive attention, and it is remarked that those developed by stream-erosion are not common, except in cases of the recession of a waterfall past the mouth of a tributary. The features are characteristic of regions recently glaciated, where, as in the western mountains of North America and elsewhere, a main valley has been deepened by glacial action below the level of tributary streams.

The work of the ocean is fully discussed and illustrated. The cutting of cliffs in different materials. the formation of arches, stacks, and beaches, and rill-marks on sands that simulate sea-weeds, and other subjects large and small come under consideration. The later chapters are occupied by "the origin and descent of rocks"; minerals and rocks are described, and some account is given of the new, and by no means popular, American petrological classification and nomenclature. Various structural features, cross-bedding, nodules, joints, folds, &c., as well as deformations, volcanic action, and other topics, are illustrated.

The geological functions of life are then dealt with. The consumption and restoration of carbon dioxide and the consequent influence on climate are discussed. The agency of organisms in the disintegration of rocks, and the protection they afford against erosion are pointed out. Attention is also directed to the influence of land vegetation on the character of sediments, due in the first place to the decomposition of different rocks and the formation of soils—materials which may be carried out to sea. On the other hand, "if the surface be bare of vegetation, the crystalline rocks are usually *disaggregated* before they are de-

composed." The bearing of these facts on the question of vegetal coverings in the earlier periods is briefly discussed. Observations on organic rocks, and on the distribution and development of the fauna and flora, lead up to the subject of historical geology, which the authors propose to deal with in another volume. H. B. W.

MACHINERY FOR HANDLING RAW MATERIAL.

The Mechanical Handling of Material. By G. F. Zimmer. Pp. xii+521; illustrated. (London: Crosby Lockwood and Son, 1905.) Price 25s. net.

IN the preface Mr. Zimmer says that he has been for twenty years professionally engaged in this branch of engineering, and he was recently induced to put together in the form of a treatise—the first in English on the subject—the mass of notes he had gradually accumulated. The importance of the subject is emphasised in the introduction by a few suggestive figures as to the amount of raw materials which has to be dealt with annually, and it may be noted that the wages of an ordinary labourer are equivalent to the interest on 1000*l.* of capital.

The question of the continuous handling of material is treated in the first section of the book; special prominence is given to elevators for the conveyance of corn and flour, and to the important problem of the supply of coke, ore, &c., to the top of blast furnaces; illustrations are given of the latest American furnace hoists. The system of band conveying, due to the inventive skill of Mr. Lyster, engineer to the Liverpool Docks, and the automatic throw-off carriage for such conveyors, also due to Mr. Lyster, are described in detail. Vibrating trough conveyors—the latest type of such machinery, and especially useful with any material which would deteriorate in rough treatment—are then dealt with. Tightening gears, power required, and speed of travel in the different types of convevors are discussed in a special chapter, thus facilitating reference and comparison. The various types of pneumatic elevators, including the successful Duckham system for loading grain which has been extensively used, are next treated. This section of the book is concluded by a series of descriptions, in every case with illustrations, of conveyors which have been designed for special purposes, such as timber conveyors, hot coke conveyors for gas works, and casting machines for use with large blast furnaces.

The intermittent handling of material, mainly by endless chains and ropes, including the many systems of aërial cable-ways, forms the second section of Mr. Zimmer's book. One of the examples selected to illustrate the use of aërial ropeways is that used during the building of the new Beachy Head Lighthouse, and full credit is given to Messrs. Bullivant for the ingenious way in which the many practical difficulties were overcome. We may mention that it is to this system of aërial ropeway that the rapid completion of that remarkable bridge which will convev the Rhodesian railways over the great gorge of the Zambesi, almost within a stone's throw of the famous falls, is due; it not only facilitated the erection of the bridge, but it also enabled the permanent way and rolling stock for the northern continuation of the railway line to be transported to the north bank of the gorge long before the bridge itself was completed. The interesting question of the coaling of ships at sea, a subject of special interest in view of the recent voyage of the famous Baltic Fleet to the East, forms the conclusion to this section.

The third section of the book is devoted to unloading and loading appliances. The discharging of vessels in docks, and the discharging of railway trucks—work requiring so much labour—have been fertile subjects of invention, and a large number of systems of grab-elevators and self-emptying trucks are described. In view of the enormous weight of coal annually shipped at the various coal shipping centres, no branch of the mechanical handling of material has received more attention than that of coal tips for loading colliers, and the chapter which treats of coal tips is a most complete and valuable one. In the last section of the book a number of miscellaneous devices, which the author has found it impossible to group under any of the previous divisions, are described, such as the automatic weighing of material, the coaling of railway engines, &c. Large flour and silo warehouses form an essential feature in the mechanical handling of raw materials such as grain and seed, and a couple of chapters, illustrated with the help of a number of plates, are given up to a detailed account of the main features of their design.

The book will be indispensable to all engineering firms, consulting engineers, and architects who have to deal with this important question either in the way of designing machinery or of erecting warehouses, and it is, though highly technical, a book which will appeal to the general reader anxious to obtain some slight knowledge of the latest advance in the mechanical handling and transport of the immense quantities of raw materials used daily in our industrial life. T. H. B.

THE BUTTERFLIES OF INDIA.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. *Butterflies.* Vol. i. By Lieut.-Colonel C. T. Bingham. Pp. xxii+511; Figs. 94; Plates 10. (London: Taylor and Francis, 1905.) Price 20s.

NINETY years ago, when Kirby and Spence published the first volume of their "Introduction to Entomology," they considered it necessary to devote a whole letter, filling many pages, to refuting popular prejudices against the frivolity and uselessness of the study of entomology; and, no doubt, at that period butterfly-collecting was looked upon as a very silly, childish pursuit; while less than 200 years before, in the time of Charles II., a serious attempt was made to set aside the will of a certain Lady Glanvil, on the ground of insanity, as shown by her fondness for collecting butterflies.

Now, however, instead of butterfly-collecting being ridiculed, it has become almost necessary to discourage it in England in order to prevent the total extermination of all our rare and local species, while abroad it is pursued with enthusiasm by travellers and colonials, some of them belonging to the highest social circles. Again, during the last fifty years, so much light has been thrown on various scientific problems by the study of butterflies that eminent professors are ready to devote a great portion of their lives to such investigations.

Of late years, many Indian officers and civilians have taken up the collection and study of the butterflies of our Indian Empire, which are probably better known at the present time than those of any other part of the world outside Europe, except North America and South Africa. But there exists no complete work on the subject suitable for the use of students. Mr. F. Moore's great works on the butterflies of Ceylon and India are very bulky and costly, and the latter is still in progress, while the regretted death of L. de Nicéville left the work commenced by himself and Col. Marshall, and subsequently carried on by de Nicéville only, complete only as regards the earlier families. Lieut.-Colonel Bingham, a retired Indian officer, who has collected insects assiduously in many parts of India, Burma, &c., and who has already published two volumes on Hymenoptera in the present series, "The Fauna of British India," has been wisely chosen to supply the existing want of a manual of Indian butterflies, and with his previous practical experience behind him, and with sufficient leisure, and access to the collections and library of the Natural History Museum at South Kensington at his disposal, the work could not have been placed in better or more competent hands.

It is expected that three volumes will be required to deal adequately with the subject. Six families are admitted by the author, of which the first two, Nymphalidæ and Nemeobidæ, are discussed in the first volume. The arrangement of the work is similar to that which has been used in previous volumes of this series dealing with insects, which are already well known to all entomologists. The introduction, necessarily brief, contains remarks on classification, metamorphoses and structure, with text-illustrations of the larva and pupa of Vanessa, the head and body of Argynnis and Charaxes, and a very useful selection of figures of labial palpi, antennæ, neuration of wings, and legs. It is worthy of special remark that the author expressly discards the term "species" as liable to mislead, and uses "form" instead, as less objectionable.

Four hundred and seventy-nine species are described in vol. i., belonging to the Nymphalidæ (with six subfamilies, Danainæ, Satyrinæ, Acræinæ, Libytheinæ, Morphinæ, and Nymphalinæ), and Nemeobidæ (five genera only).

The text illustrations are excellent, and among the more interesting ones we may note Figs. 13 and 14, on p. 40, showing the variations in shape and markings of the forewings of seven specimens of *Euploea klugii*, Moore, and Fig. 94, on p. 501, of *Stiboges nymphidia*, Butl., showing its remarkable resemblance to a species of the well-known tropical American genus Nymphidium.

Ten full-page plates (half-figures only) are added, drawn by Mr. Horace Knight and lithographed by the three-colour process by Messrs. Hentschel, and these alone are sufficient to give some idea to outsiders of the variety and beauty of the butterflies of India. If we take the butterflies of Great Britain at 70, those of Europe at 300, and those of British India, within the limits of the present work, at 1500, we shall have a fairly accurate idea of the proportions borne to each other by these three faunas.

In outlying districts, no doubt, many species still remain to be added to the Indian butterfly fauna, but apart from this, nothing is yet known of the transformations, habits, &c., of a great proportion of the insects, which will be sufficient to occupy the attention of numerous observers for many years. The metamorphoses of each butterfly, so far as yet known, are briefly noticed by Lieut.-Colonel Bingham, but it is only occasionally that he has been able to offer his readers any information of this description.

THE STATE AND AGRICULTURE.

The State and Agriculture in Hungary. By Dr. Ignatius Darányi, translated by A. György. Pp. xxii+264. (London: Macmillan and Co., Ltd., 1905.) Price 5*s*. net.

THERE are two fundamentally opposite theories of the duties of a public department dealing with a great industry such as the Board of Agriculture in this country—the one that its function is to foster the industry, the other that it is simply concerned in registering the progress and administering such legislative enactments as may be necessary from time to time.

Our English public offices have all grown up on the latter model, and the Board of Agriculture, which is always being abused for not doing this or that to improve the position of farmers, might legitimately answer that it was never designed to offer any such help to the agriculturist. Of course, the official apologists of the Board cannot put forward such a view nakedly; their plan is rather to divert the unreasonable attack by a show of activity.

To take a concrete case; the Board of Agriculture endeavours to eradicate swine fever—that it recognises as a proper function, true police work for agriculture —but supposing it should be urged to do something to improve the breed of pigs kept in England by introducing new breeds or by distributing boars of the right type in the backward districts, it would probably meet the demand by issuing a leaflet on "points to be aimed at in pig-breeding." The English method is cheap; it is also supposed to be bracing; and the English farmer, being subjected to the State-aided and bounty-fed competition of all other agricultural countries in the only open market, his own, is supposed to be in special need of a bracing *régime*.

So when people ask why the Board of Agriculture does not educate like France, or investigate like

Germany, or introduce new crops and new industries like the United States, or organise its workers like Hungary, the Board has one sufficient and final answer in the fact that such has never been the English theory of the function of a public office.

In the book before us we have an account of the policy of a man who took a different point of view, and created, perhaps, the most paternal ministry of agriculture in the world. Dr. Ignatius Darányi was Minister of Agriculture for seven years (1896–1903) in Hungary, and during his tenure of office he built up an extraordinary system of agricultural education, investigation, and organisation in Hungary. It would be impossible in the limits at our disposal to discuss either the means adopted or the results that have accrued; roughly speaking, Dr. Darányi's method in any industry was to make a start with a State-owned farm or garden, forest or mill, as the case might be. Here proceeded the investigations necessary to establish the conditions requisite for success, and from this centre issued the teachers who carried the new methods to the cultivators. The State then stepped in again, sometimes to lend the cultivator the money necessary for the fresh start, or to organise a co-operative society to enable him to realise the full advantage of the newer methods. Thus, by leaps and bounds, the whole character and quality of Hungarian agriculture has been changed. The reader will find the process set out fully with a wealth of statistical detail in Dr. Darányi's book, which takes the form of a kind of valedictory report on quitting office. It has been excellently translated by Mr. György, who, knowing so well the conditions prevailing in England, adds a preface discussing the value and limits of State interference in such matters. It is a wonderful record; to the English reader, particularly if he be a farmer, it seems difficult to believe that so much can be done for the industry, and also that the distance of a few hundred miles should render impossible in this country methods that have proved so practicable and so fruitful for the Hungarian agriculturist.

OUR BOOK SHELF.

The Treatment of Diseases of the Eye. By Dr. Victor Hanke. Translated by J. Herbert Parsons, F.R.C.S., and George Coats, M.D., F.R.C.S. Pp. vi+222. (London: Hodder and Stoughton, 1905.) Price 3*s.* 6*d.* net.

Dr. Victor Hanke, the writer of this little book, is principal assistant to Prof. Fuchs in Vienna, and the methods of this famous clinique are those which are here given to a wider public. It naturally follows that it is characterised throughout by a practical sanity which has been sadly lacking in some books on similar subjects which have recently been thought worthy of translation. The author has no special hobby-horse on which to ride to mental destruction. His treatment throughout is practical, scientific in the best sense of the word, what we may call for lack of a more fitting adjective, commonsensical. There is no rash advocacy of new and untried methods of treatment simply because of their novelty. Consequently, it is a book which can be thoroughly recommended to all practitioners of the art of medicine. Reliance on it will not lead to disappointment, for the methods advocated are thoroughly modern and sound.

A careful reading reveals practically no ground for adverse criticism, and many points for active commendation. The warning against the indiscriminate use of cocaine is one that should be unnecessary to any practising ophthalmic surgeon, and yet we have only recently seen prescriptions for lotions and drops given to patients for frequent use containing cocaine. "The immoderate use of cocaine . . . is not only unnecessary but actually harmful to the corneal epithelium"; and again, "Cocaine should in general not be used, for on the one hand its action is only transitory, while on the other it has an injurious influence on the corneal epithelium; moreover the dilatation which follows the temporary contraction of the vessels is harmful."

It would be easy to point out many places in which good results can be obtained by methods of treatment other than those recommended, but as the book does not in any way pretend to be exhaustive, and as the methods given are thoroughly sound, it would be hypercritical to do so. We doubt, however, the advisability of the use of adrenalin in severe inflammatory glaucoma, even if only given to facilitate the operation. Macallan, in a paper in the Ophthalmic Hospital reports some two or three years ago, pointed out the dangers of this drug in glaucoma, and its tendency to set up the hæmorrhagic form.

The chapter on the various forms of inflammation of the cornea and their treatment is quite the most valuable in the book, and generally the earlier chapters dealing with the external diseases of the eye are fuller than the later chapters. The reason of this is that the author does not pretend to give descriptions of operations where only "considerable skill and experience can command success," and in diseases of the deeper parts of the eye the advice of the ophthalmic surgeon is more likely to be called for, and this book is not intended for him. In conclusion, we can only reiterate what we have already stated, that students of medicine will find this a thoroughly safe guide in the treatment of diseases of the eye.

Die Stellung Gassendis zu Deskartes. By Dr. Hermann Schneider. Pp. 67. (Leipzig: Dürr'sche Buchhandlung, 1904.) Price 1.50 marks.

Gassendi and Descartes were contemporaries and fellow-countrymen, but the relation between them is mainly one of contrast. Gassendi was of peasant origin, a writer encyclopædic in his range, an *Epicurus redivivus* with all Epicurus's distrust of mathematics and all his belief in a material soul, a sceptic who was yet content to remain in the ranks of the Catholic priesthood, his face ever turned to the past whether in philosophy or religion. On the other side there is Descartes, a noble by birth, a student principally of the human understanding, something of a Platonist, with the Platonist's reverence for mathematics and numbers, a dualist who fixed a great gulf between mind and body and between man and the lower animals, an uncompromising doubter of everything but his own doubt and all that is implied by the capacity to doubt, the exponent of *cogito, ergo sum*—in a word, the representative of the distinctively modern tendencies, which mean in religion Protestantism, in science mathematical physics, in philosophy Kantianism new and old. Only in so far as modern thought inclines to atomism and materialism—and how much that is the author points out in his closing paragraph—do we find that its sympathies lie with Gassendi rather than with Descartes.

These contrasts, extended into a detailed discussion of some of the writers' most important works and particularly of their views on psychology, physics, and

ethics, are well brought out by this author. His book may be heartily recommended to students of the period described.

A Text-book of Physics, Heat. By Prof. J. H. Poynting, Sc.D., F.R.S., and Prof. J. J. Thomson, M.A., F.R.S. Pp. xvi+354. (London: C. Griffin and Co., Ltd., 1904.) Price 15s.

THE third volume of this well known text-book more than sustains the standard set by its predecessors. The volumes on sound and properties of matter have already appeared. The volumes on light and on electricity and magnetism we hope may follow at a somewhat shorter interval than has intervened between the first three volumes of the series. It is hardly necessary to say that the work is well up to date, and extremely clear and exact throughout, and that it is as complete as it would be possible to make such a text-book within the limits which the authors have laid down for the scope of their work. Among the more original features which should be valuable to the student as filling gaps which are noticeable in similar text-books, we observe that a useful chapter is included on the subject of circulation and convection, with illustrations from meteorology and ventilation. The treatment of the important subject of radiation, especially in relation to temperature and thermodynamics, is unusually complete and clear, and presents in a simple, connected form a number of most important results which the student would have difficulty in finding elsewhere. The experimental spirit is maintained throughout the work in such a manner that the student will feel that he is learning from a practical master of the subject, and will unconsciously imbibe something of the attitude of mind of the original investigator. H. L. C.

The Oxford Atlas of the British Colonies. Part i. British Africa. Seventeen maps. (Oxford Geographical Institute: William Stanford and Co., Ltd., n.d.) Price 2s. 6d. net.

THE first thirteen plates consist of coloured maps, and the remaining four are outlines intended for use as "test" maps or for other class purposes. The first map shows a hemisphere in which Cape Colony occupies the centre, and it is possible from it to see at once the relation of South Africa to the other continents. Map ii. is a political map of the world drawn in accordance with Mollweides's equal area projection, and the student will notice at a glance the apparent distortion in shape, though the relative sizes of land areas in different parts of the map are correctly shown. In addition to meteorological charts, the atlas includes physical and political maps of Africa, and maps of Cape Colony, Natal and Zululand, the Transvaal and Orange River Colony, Rhodesia, and of West, East, and Central Africa.

High Temperature Measurements. By H. Le Chatelier and O. Boudouard. Authorised translation and additions by Dr. G. K. Burgess. Second edition. Pp. xv+341. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 12s. 6d. net.

IN preparing the present edition it was found necessary to make a large number of additions, and the book now gives a useful summary of what is known about pyrometry. The advances in optical pyrometry during the last few years are recognised by the authors, and a useful chapter on the laws of radiation has been inserted. A number of pyrometers are described, but the discussion of the principles involved is in general more adequate than the description of instruments. No mention is made of some of the best of these in use in this country.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Comparison between Two Theories of Radiation.

ON two occasions (NATURE, May 18 and July 13) Lord Rayleigh has asked for a critical comparison of two theories of radiation, the one developed by Prof. Planck (*Drude's Annalen,* i. p. 69, and iv. p. 553) and the other by myself, following the dynamical principles laid down by Maxwell and Lord Rayleigh. It is with the greatest hesitation that I venture to express my disagreement with some points in the work of so distinguished a physicist as Prof. Planck, but Lord Rayleigh's second demand for a comparison of the two methods leads me to offer the following remarks, which would not otherwise have been published, on the theory of Prof. Planck.

Early in his second paper, Planck introduces the conception of the "entropy of a single resonator" S. There are supposed to be N resonators having a total entropy $S_N = NS$, and S_N is supposed to be given by $S_N = k \log W +$ constant, where W is the "probability" that the N resonators shall be as they are. Without discussing the legitimacy of assigning entropy to a single resonator, we may at present suppose S defined by $S = k/N \log W +$ cons.

The function W, as at present defined, seems to me to have no meaning. Planck (in common, I know, with many other physicists) speaks of the "probability" of an event, without specifying the basis according to which the probability is measured. This conception of probability seems to me an inexact conception, and as such to have no place in mathematical analysis. For instance, a mathematician has no right, *quâ* mathematician, to speak of the probability that a tree shall be between six and seven feet in height unless he at the same time specifies from what trees the tree in question is to be selected, and how. If this is not so, may I ask, "What *is* the probability that a tree shall be between six and seven feet high?"

When Prof. Planck calculates the probability function W, he in effect assumes that *a priori* equal small ranges of energy are equally probable. Thus he tacitly introduces as the basis of his probability calculations an ensemble of systems of resonators such that the number of systems in which the energy of any given resonator lies between E and $E+dE$ is proportional simply to dE. This, of course, he has a right to do, only he must continue to measure probability according to this same basis.

The systems of resonators are in motion, their motion being governed by the laws of dynamics. Will they, as the motion progresses, retain the statistical property which has been the cause of their introduction, namely, that the number of systems in which the energy of any given resonator lies between E and $E+dE$ is proportional simply to dE? It is easily found, by the method explained in my "Dynamical Theory of Gases" (§ 211), that in general they will not; the probability function W is not simply a function of the coordinates of the system. Prof. Planck's position is as though he had attempted to calculate the probability that a tree should be between six and seven feet high, taking as his basis of calculation an enclosure of growing trees, and assuming the probability to be a function only of the quantities six and seven feet. His ensemble of systems has not yet reached a statistical "steady state."

Prof. Planck supposes his function S to possess the property of the entropy function, so that $1/T = dS/dU$, where T is the temperature. Combining this with Planck's calculation of S, we find

$$1/T = k/\epsilon \log (1+\epsilon/U) \quad . \quad . \quad . \quad . \quad (1)$$

Here ϵ is a small quantity, a sort of indivisible atom of energy, introduced to simplify the calculations. We may legitimately remove this artificial quantity by passing to the limit in which $\epsilon = 0$. In this way we obtain

$$1/T = k/U \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Thus the mean energy of each resonator, according to this equation, is the same multiple of the temperature, no

matter how many degrees of freedom the resonator possesses, or what the form of its potential energy. Indeed, according to this argument, equation (2) is proved for any dynamical system, *e.g.* the molecules of a gas.

It is, however, known that equation (2), with Planck's meaning of k, is true if, and only if, the energy of each dynamical system is expressible as the sum of two squares. It can, indeed, be shown directly that this latter condition is exactly the condition that Prof. Planck's assumed basis of probability calculations shall be a legitimate basis, *i.e.* shall be independent of the time. Happily, this condition of the energy being a sum of two squares may be supposed to be satisfied by Planck's resonators, so that we may regard equation (1) as true for such resonators. The equation has, however, no physical meaning, owing to the presence of the arbitrary small quantity ϵ, and can acquire a physical meaning only by putting $\epsilon=0$. It then leads merely to equation (2), which can be obtained much more readily from the theorem of equipartition.

Taking $\mathfrak{u}d\nu$ to be the law of radiation, where ν is the reciprocal of the period of vibration, Planck introduces from his first paper the equation

$$\mathfrak{u}=(8\pi\nu^2/c^3)U \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

which in combination with equation (2) would lead to the law of radiation,

$$(8\pi k/c^3)T\nu^2 d\nu \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and this, on replacing ν by c/λ, becomes

$$8\pi kT\lambda^{-4}d\lambda \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

which agrees with my own result. Planck arrives at equation (3) by the help of his assumption of "näturliche Strahlung," but I believe it will be found that this "assumption" is capable of immediate proof by the methods of statistical mechanics. Except for this, and the other differences already stated, the way in which expression (5) has been reached in the present letter is identical, as regards underlying physical conceptions, with the way in which it has been obtained by Lord Rayleigh and myself.

Planck does not reach expression (5) at all, as he does not pass from equation (1) to equation (2). Instead of putting $\epsilon=0$, he puts $\epsilon=h\nu$, where h is a constant, and this leads at once to his well known law of radiation. It will now be clear why Planck's formula reduces to my own when $\lambda=\infty$. For taking $\lambda=\infty$ is the same thing as taking $\nu=0$, or $\epsilon=0$.

The relation $\epsilon=h\nu$ is assumed by Planck in order that the law ultimately obtained may satisfy Wien's "displacement law," *i.e.* may be of the form

$$\nu^3/c^3 f(T/\nu)d\nu \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

This law is obtained by Wien from thermodynamical considerations on the supposition that the energy of the ether is in statistical equilibrium with that of matter at a uniform temperature. The method of statistical mechanics, however, enables us to go further and determine the form of the function $f(T/\nu)$; it is found to be $8\pi k(T/\nu)$, so that Wien's law (6) reduces to the law given by expression (4). In other words, Wien's law directs us to take $\epsilon=h\nu$, but leaves h indeterminate, whereas statistical mechanics gives us the further information that the true value of h is $h=0$. Indeed, this is sufficiently obvious from general principles. The only way of eliminating the arbitrary quantity ϵ is by taking $\epsilon=0$, and this is the same as $h=0$.

Thus it comes about that in Planck's final law

$$\frac{8\pi ch}{\lambda^5}\frac{1}{e^{ch/k\lambda T}-1}d\lambda \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

the value of h is left indeterminate; on putting $h=0$, the value assigned to it by statistical mechanics, we arrive at once at the law (5).

The similarities and differences of Planck's method and my own may perhaps be best summed up by saying that the methods of both are in effect the methods of statistical mechanics and of the theorem of equipartition of energy, but that I carry the method further than Planck, since Planck stops short of the step of putting $h=0$. I venture to express the opinion that it is not legitimate to stop short at this point, as the hypotheses upon which Planck has worked lead to the relation $h=0$ as a necessary consequence.

Of course, I am aware that Planck's law is in good agreement with experiment if h is given a value different from zero, while my own law, obtained by putting $h=0$, cannot possibly agree with experiment. This does not alter my belief that the value $h=0$ is the only value which it is possible to take, my view being that the supposition that the energy of the ether is in equilibrium with that of matter is utterly erroneous in the case of ether vibrations of short wave-length under experimental conditions.

J. H. JEANS.

On the Spontaneous Action of Radium on Gelatin Media.

SINCE my communication to NATURE on the subject of the experiments in which I have been for some time past engaged, my attention has been directed to the fact that M. B. Dubois, in a speech at Lyons last November, stated that he had obtained some microscopic bodies by the action of radium salts on gelatin bouillon which had been rendered "aseptic," but in what manner it is not stated.

I write to direct attention to the fact, as also to add that M. Dubois's experiments were quite unknown to me.

Moreover, the theory that some elementary form of life, far simpler than any hitherto observed, might exist and perhaps be brought about artificially by "molecular and atomic groupings and the groupings of electrons"—in virtue of some inherent property of the atoms of such substances as radium—was pointed out in my article on the "Radio-activity of Matter" in the *Monthly Review*, November, 1903, whilst the experiments which I have been carrying out to verify this view have been for a long time known in Cambridge.

Although I did not make a speech on the subject, I demonstrated the growths to many people at the Cavendish and Pathological laboratories early in the Michaelmas Term last year.

So momentous a result as it seemed required careful confirmation, and much delay was also caused in taking the opinions of various men of science before I ventured to write to you upon the subject.

That M. Dubois's experiments have been made quite independently I do not entertain the slightest doubt.

Some critics have suggested that these forms I have observed may be identified with the curious bodies obtained by Quincke, Lehmann, Schenck, Leduc and others in recent times, and by Rainey and Crosse more than half a century ago; but I do not think, at least so far as I can at present judge, that there is sufficient reason for so classifying them together. They seem to me to have little in common except, perhaps, the scale of being to which as microscopic forms they happen to belong.

JOHN BUTLER BURKE.

The Problem of the Random Walk.

CAN any of your readers refer me to a work wherein I should find a solution of the following problem, or failing the knowledge of any existing solution provide me with an original one? I should be extremely grateful for aid in the matter.

A man starts from a point O and walks l yards in a straight line; he then turns through any angle whatever and walks another l yards in a second straight line. He repeats this process n times. I require the probability that after these n stretches he is at a distance between r and $r+\delta r$ from his starting point, O.

The problem is one of considerable interest, but I have only succeeded in obtaining an integrated solution for *two* stretches. I think, however, that a solution ought to be found, if only in the form of a series in powers of $1/n$, when n is large.

KARL PEARSON.

The Gables, East Ilsley, Berks.

British Archæology and Philistinism.

AT the end of the second week in July two contracted skeletons were found in a nurseryman's grounds near the famous British camp at Leagrave, Luton. Both were greatly contracted; one, on its right side, had both arms straight down, one under the body the other above; the other skeleton lay upon its left side, with the left hand

under the face and the right arm straight down. Both were probably female, and upon the breast of one was a fine bronze pin seven inches long with three pendant ornaments, and three discs of bronze, one plated with gold. Other bronzes of great interest were found with the second skeleton.

I do not write to describe the bones and ornaments, but to make public the conduct of the Luton authority. A most intelligent workman lives close to the site of the discovery—one Thomas Cumberland—a man who has studied the antiquities of the district for many years, and to whom antiquaries are indebted for great and freely given assistance. This man was on the spot at once, and clearly and correctly stated the age of the bones and ornaments as British or late Celtic. Notwithstanding this information, the local police insisted on an inquest, although the bones were broken to pieces and in the highest degree friable. I went to the nursery and confirmed Mr. Cumberland's determination, made drawings of the bronzes, and such an examination of the bones as circumstances would permit. The coroner refused to hold an inquest, and so had no authority to make any order, but he wrote and "suggested" that the bones should be buried in the parish churchyard. Armed with this "suggestion," the relieving officer ordered an undertaker to carry off the bones, which he did, in spite of the protest of the nurseryman, who informed him that they had been given to me and were my property. He was ordered to put the bones in coffins and bury them in the churchyard of Biscot. The undertaker took the bones to his shop at Luton. I at once applied to the relieving officer for permission to examine and measure some of the bones. I clearly explained to him the nature and importance of the discovery, and the trifling nature of the favour asked. This official replied in a curt and rude manner, and simply said, "I have no authority; you must apply to the coroner."

I repeatedly wrote to the undertaker to delay the funeral for a few days. I twice wrote to the coroner in an urgent but most respectful manner, and pointed out the importance of the discovery, which, indeed, is quite unique in this district, but all to no purpose. He said he had not given the "order" for burial, and he refused to interfere, but he wrote to the undertaker and said, "I can give no consent or authority in any way, but must leave you to carry out the arrangement which has been come to with you." I wrote letters for six days to the different persons concerned, but to no effect; they would have a funeral, and the police now actually demanded the bronzes from the owner. The property is freehold.

Well, on Wednesday last the two coffins were screwed up at Luton and taken in a hearse to Biscot churchyard, where the vicar, in the presence of a policeman, officiated. Shining breastplates were screwed on to the coffins inscribed, "Bones found at Leagrave, July 1905." Amongst the bones in the coffins were several non-human examples, a rib bone of a sheep, a piece of a rib of beef, a bone of a rabbit, and another of roebuck.

Dunstable. WORTHINGTON G. SMITH.

Graphical Solution of Cubic and Quartic Equations.

SOME years ago you published some interesting communications in regard to the graphical solution of cubic and quartic equations (vol. lxi. p. 55, vol. lxiii. pp. 515 and 609, vol. lxiv. p. 5). The solutions then given give only the real roots of the equation. I therefore take the liberty of directing attention to the following method, which gives the roots of cubic and quartic equations whether the roots are real or complex, and may be applied to equations of higher degree, with more complicated results.

A cubic equation with real coefficients may be reduced by a simple real transformation to the form

$$z^3+qz+1=0,$$

where q is real, and since the sum of the roots of this equation is zero, they may be written in the form

$$\begin{gathered}-2y\\ y+\sqrt{x}\\ y-\sqrt{x}.\end{gathered}$$

If, now, we form the symmetric functions, we have

$$\begin{gathered}3y^2+x=-q\\ 2(y^3-xy)=1.\end{gathered}$$

Hence if we draw the fixed curve

$$y^3-xy-\tfrac{1}{2}=0,$$

the coordinates of the points where it is cut by the movable parabola

$$3y^2+x+q=0$$

give the roots of the equation

$$z^3+qz+1=0,$$

i.e. if x_0 and y_0 are the coordinates of any such point, $-2y_0$ and $y_0\pm\sqrt{x_0}$ are the roots of the given equation.

In like manner a quartic equation with real coefficients may be put into the form

$$z^4+qz^2+z+s=0,$$

where q and s are real, and its roots may be put into the form

$$\begin{gathered}v\pm\sqrt{w_1}\\ -v\pm\sqrt{w_2}\end{gathered}$$

and, forming the symmetric functions, we have

$$2v^2+w_1+w_2=-q \quad \ldots \quad (1)$$
$$2v(w_1-w_2)=-1 \quad \ldots \quad (2)$$
$$v^4-(w_1+w_2)v^2+w_1w_2=s \quad \ldots \quad (3)$$

and if we put

$$\begin{gathered}4v^2=y\\ (w_1-w_2)^2=x\end{gathered}$$

we find by simple elimination

$$xy=1,\ (y+q)^2-(x+4s)=0.$$

Hence the intersections of the fixed hyperbola with the movable parabola give values for x and y from which v, w_1, and w_2 may be calculated.

If we eliminate x from the two equations last written, we have

$$y^3+2qy^2+q^2y-4sy-1=0.$$

Hence there is always at least one positive value for y, therefore a real value of v; also, since $xy=1$, a positive value for x, therefore a real value for w_1-w_2; and since from (1) w_1+w_2 is real, real values for w_1 and w_2.

H. IVAH THOMSEN.

1928 Mt. Royal Terrace, Baltimore, Md., June 7.

THE PRESENT POSITION OF THE CANCER PROBLEM.

THE term "cancer" is in common parlance indiscriminately applied to all tumours the growth of which is unlimited and generally rapid, which tend to recur after removal by operation, and particularly which reproduce their like (the secondary or metastatic growths) in parts of the body remote from the original seat of disease. Pathologically there are various forms of "cancer," or malignant disease, but there is no need to deal with these here, and it may be stated that there is no sharp line of demarcation between the so-called benign and the malignant growths; there is a series of connecting links between the two. Malignant disease is an important cause of death. According to the last published report of the Registrar General (1903), the death-rate from this cause per 1000 living was 0·87; for comparison that for pulmonary tuberculosis (consumption) may be quoted; this was 1·2.

Moreover, it is a common belief that cancer is on the increase; people remark how much more frequently it is heard of now than formerly, and apparently the statistics support this view, for the cancer death-rate, which was 0·56 in 1884, has steadily increased, and is now 0·87, as stated above. Competent statisticians, however, doubt whether the increase is real or only apparent, and partly due to more accurate diagnosis and to a greater tendency to seek medical advice. During the last two or three decades surgery has made

enormous strides, and it may be said that no region of the body is now beyond surgical interference. Many more obscure conditions, therefore, come under observation than formerly, and the vast majority of tumours removed by the surgeon are in the present day examined microscopically and their nature ascertained without doubt. In the Registrar General's Report for 1903 (p. 63), the various corrections which have to be made to obtain even an approximate corrected rate will be found. It is also to be noted that the deaths classed under "ill-defined causes," which doubtless included many cases of obscure malignant disease, have steadily fallen. Of 49,555 deaths from ill-defined causes in 1903, further inquiry showed that 439 were due to malignant disease. If these inquiries had not been made, which was formerly the case, these 439 deaths would have been omitted, and the cancer death-rate would have been correspondingly diminished. The statement is definitely made in the report of the Imperial Cancer Research Fund just issued that it is not yet possible to determine statistically whether cancer has really increased.

Cancer attacks rich and poor alike, and the manner in which it progresses to a fatal issue, unless early treated by radical operation, has caused it to be regarded with dread by all. It attacks all races of men, though the savage races seem less susceptible than the civilised, and it is met with throughout the vertebrate kingdom. There is no evidence that any form of diet or mode of life conduces to cancer-formation. The origin of cancer has for long exercised the minds of pathologists, and it is in particular the true cancers or epithelial tumours which have been the subject of most research.

The alleged causes of the origin of cancer may be divided into entogenous or intrinsic, spontaneous and anomalous changes within the organism, and ectogenous or extrinsic, derived from outside the body. Of the entogenous theories the most important are those of Thiersch and of Cohnheim. Thiersch suggested that tumour formation consisted in a loss of balance between the epithelial cells and connective tissue, whereby the former take on abnormal and undirected growth. Cohnheim referred the origin of cancer to embryonic cells which had for some unknown reason remained in an undeveloped state and become included in the tissues, and which subsequently proliferate and form the primary growth. Ectogenous theories ascribe the formation of malignant growths to the action of micro-parasites, and bacteria, yeast and other fungi, and protozoa have in turn been regarded as the causative organisms. There are, it is true, some analogies between certain microbic conditions and cancer formation, but the fact that it is a portion of the original growth conveyed by the blood and lymph to distant parts which causes the secondary growths, and that the tissues at the site of the secondary growth take no part in its formation, is quite different from what obtains in microbial affections. Attempts have been made to prove that cancer is contagious, and it is known that the disease is more prevalent in certain districts than in others, which lends some support to the parasitic theory. Auto-infection undoubtedly occurs; a cancer of the breast may infect the neighbouring arm, or of a lip the other lip, and cancer of mice can readily be inoculated into other mice, but these instances of apparent inoculation are rather of the nature of a transplantation; in the mouse it is the tissue introduced which increases and forms the malignant growth, not the tissue of the inoculated animal. Experiments by the staff of the Imperial Cancer Research Fund prove that healthy mice kept in close contact with cancerous mice never contract the disease.

The cancer of one animal is inoculable only into another animal of the same species, and human cancer, therefore, cannot be transmitted to the lower animals. All attempts to isolate a micro-parasite have proved failures, in spite of the vast amount of work done in this direction. The alleged organisms of cancer, such, for example, as certain yeast fungi, have, it is true, been found to produce tumour-like growths, but these have, on critical examination, been proved to be of the nature of granulomatous growths, and not true cancer. A point of which a good deal has been made by the supporters of the parasitic theory is that the so-called "cancer bodies," the alleged parasites, are present only in malignant growths, and not in normal or pathological tissue nor in benign tumours. But the deduction from this fact, that these bodies are therefore parasitic, has little to support it when it is considered that cancer is a unique tissue, and might obviously contain structures not found elsewhere and not necessarily parasitic. On these and other grounds the parasitic theory has of late steadily been losing ground.

The remarkable observations of Prof. Farmer and Messrs. Moore and Walker have recently thrown much light on the possible nature of the cancer process. As detailed in these columns (February 4, 1904, p. 319), it is found that in cancerous tissues many at least of the cells divide in a manner quite different from that of the somatic or body cells generally. This mode of cell-division observed in cancer is that which obtains in gametogenic or sexual reproductive tissue, and is characterised by a difference in the mode of division (transverse instead of longitudinal) and in the number (sixteen instead of thirty-two for man) of the chromatin bands or chromosomes of the nucleus, and is known as "heterotype mitosis." The division succeeding the heterotype, known as the homotype, still retains the reduced number of chromosomes, and is, therefore, sometimes termed "reduction division." Cells with reduction division do not seem to be able to regain the somatic mitosis except by fertilisation. This gametogenic-like tissue of malignant growths has been termed "gametoid." Other irregularities in division of cancerous cells also occur.

Another remarkable fact recently demonstrated by Messrs. Farmer, Moore, and Walker (NATURE, June 15, p. 164) is that in the normal reproductive tissues structures occur which are strikingly similar to the bodies ("cancer bodies") described by Ruffer, Plimmer, and others in cancerous growths, and regarded by many as parasites. These structures in the reproductive tissues are the archoplastic vesicles, and that similar structures should occur in cancerous growths (and not, be it noted, in benign tumours) on the one hand lends additional support to the idea of the gametoid nature of the cancer cells, and on the other further disproves the supposed parasitic nature of the "cancer bodies."

Is it possible from these observations to formulate a suggestion as to the nature of the cancer process? Prof. Farmer himself has stated that he and his co-workers do not profess to explain the relation between the heterotype mitosis of the gametoid cells of cancer and the life-history of cancer. It might be that the gametoid cells of the malignant growth undergo some process of fertilisation giving rise to an aberrant embryo, as it were, which by development forms the primary growth, which would thus be parasitic on the host, the secondary growths arising from a repetition of the primary event. In some plants gametogenic tissue may normally possess parasitic characteristics. There is, however, so far little evidence of fertilisation or fusion of the gametoid cells in cancer,

except that, as recently stated by Mr. Moore (*Brit. Med. Journ.*, July 8, p. 104), leucocytes or white blood cells are sometimes found within the body of the cancer cells, with which they appear to be undergoing conjugation.

Messrs, Farmer, Moore, and Walker suggest that it is possible that the malignant elements are the outcome of a phylogenetic reversion, but this would not necessarily explain the *invasiveness* of cancer. In spite of recent work, much remains to be done and to be explained before we shall be in a position clearly to understand the cancer process.

With regard to the causes which lead to the production of the gametoid cells in cancer, it has been found that in plants various stimuli will rapidly bring about heterotype mitosis, and, given the proper stimulus, probably any somatic cell may become changed into this type. The connection between chronic irritation and cancer has long been recognised, but the manner in which this factor acts to produce cancer has not been understood; but in the light of the foregoing, it may be regarded as one of the stimuli which may bring about heterotype mitosis and reduction division.

Does recent work hold out a prospect of the discovery of a curative agent for cancer? It cannot be said that our hopes in this direction have been materially increased as yet. At present almost the only hope of cure lies in early and radical operation, and it is of the greatest moment that the public should realise the importance of early treatment, and that no time should be lost in seeking advice. In superficial cancers, the X-rays and radium emanations seem to effect a cure by causing a retrogression or a necrosis of the cancer elements. Possibly the gametoid tissue of the cancer is more vulnerable than the somatic cells, and hence the former may be caused to degenerate or be destroyed without materially injuring the latter, but probably the rays cause proliferation of the connective tissue elements of the growth and interfere with its nutrition. Is it possible that the stimulus of these rays may also act like fertilisation, and causes the gametoid once more to revert to somatic cells, which then being of the nature of a foreign body are partly removed and partly remain inert?

Clowes and Gaylord (Bulletin of the Johns Hopkins Hospital, April, 1905) have observed that cancer in mice occasionally undergoes spontaneous retrogression and cure, and the same occurs, but, unfortunately, only too rarely, in human cancer. Clowes found that the blood serum of the mice in which this spontaneous cure had occurred exerted a marked curative action on other mice suffering from the disease. This suggests the possibility that work of a similar nature may eventually lead to the discovery of a means of treating human cancer, but the probability is small, for it is extremely unlikely that the serum of any animal would have the slightest effect on the human being. A spontaneously cured human being would almost certainly have to provide the serum!

R. T. HEWLETT.

BRITISH FRUIT GROWING.

THE report to the Board of Agriculture of the departmental committee appointed to consider what measures can be taken for the promotion and encouragement of fruit culture in these islands has been issued. The commissioners recommend that a special department should be formed to deal with matters relating to the fruit industry, and that this department should be subdivided into (*a*) a bureau of information; (*b*) an experimental fruit farm. The desirability of encouraging the practice of gardening in schools in the rural districts is also alluded to, and this recommendation will be generally concurred in. Legal questions connected with the tenancy and rating of land used in fruit culture are of cardinal importance, as also are those relating to the carriage of fruit by rail and to the alleged unfair treatment by the companies of the home-grower as compared with his foreign competitor. The necessity of further market accommodation is likewise insisted on.

These are all matters of importance, but they do not cover the whole of the ground. We find no reference in the report before us of the influence of the weather on the fruit crops, and yet this is a factor the potency of which outweighs all others. In the case of hardy fruits, not grown under glass, the fruit grower is in the main powerless to contend against adverse conditions. The tabulated reports from every county in the British Islands, which have been published annually for the last forty or fifty years in the *Gardeners' Chronicle,* bear ample testimony to this. Spring frosts when the trees are in blossom occur more or less every year, and when they happen to be severe, as they were this year, the results are disastrous. The reports from the cherry-growing districts of Kent this year show remarkable diversity of yield from farms in the same neighbourhood, a diversity due presumably to differences of shelter and aspect. It is difficult to see how the grower can protect himself from these adverse conditions. Experimental farms such as are recommended by the commission, and of which one is in operation at Woburn under the auspices of the Duke of Bedford, are for the most part of local value only; the lessons they teach may not be applicable in the next parish where the conditions are different.

Can nothing, therefore, be done? We should be sorry to assent to such a proposition. We believe that something could be done. But then arises the question whether, in the face of the vast importations first from the American continent, and when supplies from that quarter are exhausted, from Tasmania and Australia, any steps which the British grower could take would be of any use, commercially speaking? Again, no competition on the part of the home-grower is possible with the banana imports from the Canaries and the West Indian islands, which are assuming such vast proportions, or with the still larger importations of oranges. The case is different when what are termed soft fruits are concerned. We can hold our own with strawberries, raspberries, and currants, whilst gooseberries, especially when picked in a green condition, are among the most profitable crops that a farmer or even a cottager can grow. Spring frosts do them relatively little harm, so that a crop of some sort can generally be relied on.

From a commercial standpoint, when we talk of our home fruit-crops we mean apples or plums, and reverting to the subject of spring frosts we may well inquire whether it is not possible for our experts to raise breeds which shall be immune from injury. Our American cousins hoped for great things by the introduction of Russian apples, and some were tried here also, but the results were not encouraging, as the quality of the fruit was so indifferent that the experiment was not continued. Another lesson from the same source seems more promising. When a few years ago a "big freeze" occurred in Florida, the orange plantations suffered exceedingly. What did our friends do? Did they abuse the fickleness of their climate and take their misfortunes with the resignation of the fatalists? Not so. They set to work without loss of time to raise by means of cross-breeding a hardy variety, and they have at least made a good beginning. So, too, have our friends the

French, who by the cross-fertilisation of the hardy *Citrus triptera* and an ordinary orange have succeeded in producing a hardy variety of that fruit. Matters are as yet only in the experimental stage, but the possibility of success has been demonstrated. There is no reason whatever why our own experimentalists should not succeed with apples and plums. Earlier varieties, later varieties, hardier varieties, are all well within the range of possibility, and would be certainly forthcoming if we abandoned our present methods of chance selection and haphazard cross-breeding in favour of careful experiment and rational procedure.

Not only are experimental farms wanted for local purposes, but research stations wherein results might be obtained of universal application.

The Royal Horticultural Society has in its new garden at Wisley, presented by Sir Thomas Hanbury, a splendid opportunity before it, and it is to be hoped that it will not be backward in turning it to account. The fruit farm at Woburn, to which allusion has already been made, sets an example which might be followed and extended with advantage. Already important results with reference to the employment of manures have been obtained there which, though of a negative character, are none the less valuable.

NOTES.

THE annual meeting of the British Medical Association began at Leicester on Monday last. On Tuesday, Dr. G. Cooper Franklin, the president for the year, delivered his address, and the association's gold medal of merit was presented to Sir Constantine Holman and Dr. Andrew Clark. The Stewart prize was presented to Mr. W. H. Power, C.B.

THE British Electro-Therapeutic Society is holding a three days' meeting at Leicester this week. The following subjects are announced for consideration :—the present position of the treatment of carcinoma and sarcoma by electrical methods, neurasthenia, the X-rays in the diagnosis of pulmonary disease, and stereoscopic radiography, while a report will be given on the milliamperemeter as a measure of X-ray production.

THE forty-second annual meeting of the British Pharmaceutical Conference was opened at Brighton on Tuesday last. The organisation, it will be remembered, is distinct from the Pharmaceutical Society, and is solely concerned with "the encouragement of pharmaceutical research, and the promotion of friendly intercourse and union amongst pharmacists." The president, Mr. W. A. H. Naylor, delivered his address, and the reading and consideration of papers took place. The meeting terminates to-day.

SEVERAL earthquake disturbances are reported. According to a Central News telegram from Vienna, the seismograph at the Pola Hydrographic Station registered between 3.55 a.m. and 4.17 a.m. on Sunday last the occurrence of a severe and protracted seismic disturbance at an estimated distance of some 3720 miles, and telegrams from St. Petersburg, through Reuter's Agency, state that earthquakes occurred in Siberia at the following places and times :—at Chita at 10.25 on Sunday morning last; at Marünsk, in the Government of Tomsk, at about 9 a.m. of the same day; and at Kiakhta at 10 o'clock on the morning of Tuesday last. An earthquake is stated also to have taken place at Menstrie and Blair-Logie, and to have been felt in other parts of Scotland, shortly after midnight of Sunday last.

THE committee appointed in April last to consider the advisability or otherwise of confederating the principal London medical societies has now presented its report (one favourable to confederation), which, with certain minor alterations and additions, has been adopted. According to the *British Medical Journal*, it is suggested that the new society should be known as either the Royal Society of Medicine or the Royal Academy of Medicine, and that at first it should comprise the following sixteen sections :—(1) anæsthetic; (2) clinical; (3) dermatological; (4) diseases of children; (5) epidemiological; (6) laryngological, otological, and rhinological; (7) medical; (8) mental medicine (psychiatry); (9) neurological; (10) obstetrical and gynæcological; (11) odontological; (12) ophthalmological; (13) pathological; (14) State medicine; (15) surgical; (16) therapeutical, including general therapeutics, pharmacology, electrotherapeutics, balneology, and climatology. The hope is expressed that in the early future an anatomical and physiological section may be formed.

THE arrangements for the meeting in London of the International Statistical Institute, which is to take place from July 31 to August 4, are now practically complete. The proceedings will be opened at the Imperial Institute by the Prince of Wales, who will deliver an address. Addresses will also be given by the president of the institute, Dr. von Inama-Sternegg, and by the president of the Royal Statistical Society, the Earl of Onslow, after which the following communications will be presented and discussed :—superficie et population du monde; balance économique des nations; mortalité des grandes villes; statistique de la tuberculose; fécondité des mariages; statistique des transports internationaux; accidents du travail; international comparison of workmen's wages; recensements industriels et statistique du chômage; l'enseignement supérieur; import and export statistics; répercussion des droits de douanes; international agricultural statistics; valeurs mobilières; some subjects connected with pauperism; and discours sur l'avenir de la statistique.

PARTICULARS have been issued as to the arrangements which have been made for the autumn meeting of the Iron and Steel Institute. The meeting will be held at Sheffield from September 26 to 29, and the following papers have been offered for reading :—On the metallurgical department of Sheffield University, by Prof. J. O. Arnold; on the thermal transformation of carbon steels, by Prof. J. O. Arnold and A. McWilliam; on the nature of troostite, by Dr. C. Benedicks; on the occurrence of copper, cobalt and nickel in American pig irons, by Prof. E. D. Campbell; on pipe in steel ingots, by J. E. Fletcher; on steel for motor-car construction, by L. Guillet; on the presence of greenish-coloured markings in the fractured surface of test pieces, by Captain H. G. Howorth, R.A.; on overheated steel, by A. W. Richards and J. E. Stead, F.R.S.; on segregation in steel ingots, by B. Talbot; on a manipulator for steel bars, by D. Upton; on machinery for breaking pig iron, by C. Walton; on the influence of carbon on nickel and iron, by G. B. Waterhouse.

THE congress of the International Society of Surgery will this year be held in Brussels. The meetings will take place from Monday, September 18, to Saturday, September 23, and will be under the presidency of Prof. Theodor Kocher, of the University of Berne. Among the subjects to be discussed are :—the value of the examination of the blood in surgery; the treatment of prostatic hypertrophy; surgical intervention in non-cancerous diseases of

the stomach; treatment of articular tuberculosis; the treatment of peritonitis; and the diagnosis of surgical diseases of the kidney. The official languages of the congress are English, French, German, and Italian. The English delegate is Mr. R. Harrison, 6 Lower Berkeley Street, W.

Science gives particulars of the sixth International Congress of Applied Chemistry, which is to take place in Rome in the spring of next year. The congress will be divided into eleven sections as follows:—Analytical chemistry, apparatus and instruments; inorganic chemistry and industries related thereto; metallurgy and mining, explosives; organic chemistry and industries related thereto; technology and chemistry of sugar; fermentation and starch; agricultural chemistry; hygiene; photochemistry, photography; electrochemistry, physicochemistry; laws, political economy and legislation in relation to industrial chemistry. The languages to be used in the discussion are Italian, French, German, and English. The minutes of the proceedings of the session will be in Italian. The secretary of the congress is Prof. V. Villavecchia, Central Customs Laboratory, Rome.

IT is stated in *La Nature* that the seventh International Congress of Zoology is to be held at Boston, U.S.A., in August, 1907, under the presidency of Prof. Agassiz. The Emperor Nicolas II. prize will be awarded on this occasion for monographs on the subject "Nouvelles recherches expérimentales sur la question des hybrides." The essays, either in manuscript or printed, should be addressed before June 1, 1907, to Prof. R. Blanchard, boulevard Saint-Germain, 226, Paris. The essays should be in French, though those written in German, Italian, or English will be admitted to the competition if accompanied by a summary in French.

IT has been decided by the Government of New Zealand to hold during the summer of 1906–7 (*i.e.* from November, 1906, to April, 1907) at Christchurch an international exhibition in which all nations are invited to participate. The object of the exhibition is educational, and to demonstrate the resources of the colony in food production, yield of minerals, the supply of raw materials, &c. Intending exhibitors may obtain full particulars from the secretary of the exhibition at Christchurch, New Zealand.

THE report of the special committee appointed by the Government of Bombay to consider the question of a public museum and library for Bombay has been issued. The estimated initial cost of the buildings alone is approximately ten lakhs, four of which are for the building devoted to art and archæology, and three for the science museum and public library respectively.

THE Paris correspondent of the *Lancet* states that a permanent committee to deal with the watering places and climatic stations in France has just been established by the Minister of the Interior. The committee, the honorary president of which is the Minister of the Interior, is to examine into the general needs of the places referred to, and to protect and develop them. The mayors and the medical men of the various watering places, the directors and the com: ittees of *sociétés thermales*, are liable each in his turn t. be summoned to serve on the committee for a period no. exceeding three years.

THE sum of 150,000 kroner has been given by Dr. F. G. Gade, of the University of Christiania, to the city of Bergen for the establishment of a laboratory of pathological anatomy.

IT is intended to celebrate the jubilee of Prof. D. I. Mendeléeff on August 30, this eminent man of science having completed his fiftieth year of public professional service on June 13 last.

M. J. DYBOWSKI, inspector-general of agriculture in the French colonies, has been elected an officer of the Légion d'honneur, and Dr. Giraud, head of the scientific mission to Martinique, has been raised to the dignity of chevalier.

A PORTRAIT medallion, in marble, of Sir William Geddes, the late principal of the University of Aberdeen, has been completed, and will be placed in the Geddes transept of the library at King's College. Its unveiling will probably take place at the beginning of the winter session. A meeting in furtherance of the proposed memorial to the late Prof. James Nicol was held recently in Marischal College, when a number of letters from geologists and old pupils of Prof. Nicol were read, the general tenor of which favoured the placing of a portrait tablet in bronze in the geological museum. There will be, it is hoped, a formal inauguration of the memorial during the centenary celebrations of next year.

THE council of the Royal Meteorological Society, being desirous of advancing the general knowledge of meteorology and of promoting an intelligent public interest in the science, has appointed a lecturer who is prepared to deliver lectures to scientific societies, institutions, and schools on payment of a moderate fee and the cost of travelling expenses, the subjects being:—how to observe the weather; weather forecasting; climate; rainfall; thunderstorms; meteorology in relation to agriculture, health, &c. The society is also prepared to lend and fit up a complete climatological station for exhibition, showing the necessary instruments in position and ready for use, and to lend in return for a nominal amount sets of lantern slides illustrating meteorological phenomena. Further particulars as to the scheme can be obtained from the assistant secretary of the society.

IN the report for 1904 of the hydrographer of the Admiralty which has just been issued as a Parliamentary paper, reference is made to the retirement, after twenty years' service, of Rear-Admiral Sir W. J. L. Wharton, K.C.B., F.R.S. During the year under review, 482 rocks and shoals dangerous to navigation were reported. Of these 65 were notified by surveying vessels, 31 by other ships in the British Navy, 8 by vessels not in the navy, 26 were struck, and 352 were reported by colonial and foreign Governments; 1139 miles of coast line were charted, and an area of 3993 square miles sounded. During the year the number of charts printed for use in the Royal Navy, the Government departments, and by the public reached the total of 661,590 copies, and 1245 notices to mariners were issued.

THE vast deposits of magnetic iron sands in the province of Taranaki, in New Zealand, containing 60 per cent. of iron and 8·14 per cent. of titanic acid, have long attracted the attention of metallurgists, and numerous attempts have been made to smelt the ores by making them into bricks by the admixture of various substances. In 1873 works on which 17,350*l.* were spent proved a failure. A new departure has now been made by the Galbraith Iron and Steel Company, Ltd., of Auckland, by adopting the electric furnace for the direct production of steel from these sands, and by invitation of that company we were afforded an opportunity of witnessing the furnace in operation at the Brush Electrical Engineering Company's works at Loughborough, Leicestershire, on July 19. In the furnace in-

vented by Mr. D. R. S. Galbraith, a constant stream of iron sand mixed with a given quantity of carbon is fed in at the top of the furnace, and travelling downwards by gravitation falls between and upon graphite bars forming resistances in the circuit, and finally leaves the furnace in the form of molten metal. The power is supplied by a single-phase alternator having an output of 100 kilowatts at 300 volts. This pressure is reduced to 18 volts by means of a transformer in close proximity to the furnace. The plant is, of course, an experimental one, and will require to be modified in several ways before it is used on a commercial scale.

DR. J. JOLY, F.R.S. (*Scientific Proceedings of the Royal Dublin Society*, vol. x., No. 34), being struck by the difficulties raised by the silting up of harbours on the south-east Irish coast, suggests the use of floating breakwaters moored to the bottom, but sufficiently deep to prevent response to the rise and fall of waves. They would thus be affected only by the tidal movements, and the dimensions "need not be extravagant where the conditions are not such as to require protection from deep-water waves." Two types are illustrated, the one cylindrical, with a submerged platform below, going down to about four fathoms, and the other more like a flat-bottomed ship, wider below and narrower above, with a hold full of water to increase the inertia. The author believes that in the seas inside the banks of Wicklow and Arklow such a mass might be assumed to be unaffected by wave-motion. The presence of such a breakwater, it is suggested, might even favourably increase the tidal scour.

WE have received from the Home Office part iv. of the general report on mines and quarries for 1903, containing comparative statistics relating to persons employed, output, and accidents at mines and quarries in the British colonies and in foreign countries. A good idea is given of the relative importance of mining in each country. In 1903 the number of persons engaged in mining and quarrying was 4,861,932, of which one-fifth were employed in the United Kingdom and one-third in the British Empire. More than half the total were employed in getting coal, of which the world's production was 881,002,936 tons. The world also produced 609,985 tons of copper, 491,672 kilograms of fine gold, 44,548,962 tons of pig iron, 892,899 tons of lead, 26,232,099 tons of petroleum, 12,818,253 tons of salt, 4,997,491 kilograms of fine silver, 98,295 tons of tin, and 570,440 tons of zinc. The death-rate from accidents throughout the world in 1903 is estimated at 1·87 per 1000, as compared with 1·93 per 1000 in 1902. For coal mines the accident death-rate of the United Kingdom is 1·26, and for the British Empire 1·33; while for France it is 1·02, for Germany 2·00, and for the United States 3·09. The death-rate for foreign countries generally is 2·14. It is evident that mining is conducted in Great Britain with a far smaller risk of accident to the workers than in most other countries.

THE meteorological results deduced from the observations taken at the Liverpool Observatory, Bidston, for the year 1904 have been published by Mr. W. E. Plummer. This observatory is maintained by the Mersey Docks and Harbour Board, and is one of the oldest and best equipped in the United Kingdom. Many years ago, the late Mr. W. W. Rundell prepared an elaborate discussion of the winds of Liverpool, which was published by the Meteorological Office. We notice that at the present time much attention is paid to this subject, which is naturally of the greatest importance for the shipping of the Mersey. Three anemometers of the Osler, Robinson, and Dines patterns are kept in efficient operation, and the maximum velocities and extreme pressures of the wind on the square foot are given for each day of the year, while the monthly and yearly summaries of the principal meteorological elements are expressed in imperial and metric measures. In the astronomical department, the transit instrument has been used continuously for the determination of time, and 2586 stars were observed during the year.

WE have received the annual report of the director of the Royal Alfred Observatory (Mauritius) for 1904; it contains the means and extremes of the meteorological elements and other general information; the actual observations will be published in a separate volume. From a table showing the observations of the direction of the various types of clouds, it is noteworthy that out of 821 observations the cumulus cloud was observed on 397 occasions, the cirrus cloud on only 66 occasions. The mean annual rainfall at ten selected stations was 13 inches below the average. The log-books of ships visiting the island were copied, and a daily journal of the weather over the Indian Ocean kept; it is noticeable that the number of vessels arriving annually between 1882 and 1904 have steadily decreased from 686 to 262. Photographs of the sun were taken daily whenever possible; 638 negatives were forwarded to the Solar Physics Committee. During the year 65 earthquakes were recorded. The observatory is still much troubled by depredations of white ants; numerous poisons have been tried for their extermination, the most efficacious being a solution of sal-ammoniac, turpentine, and methylated spirit, while the bookshelves are insulated with castor oil.

ONE of the scientific results of the annexation of the Philippines by the United States is the study of the ethnography of the group. Mr. W. Allan Reed has published a report on the Negritos of Zambales (vol. ii., part i., Ethnological Survey Publications, Manila, 1904). This is in reality only a sketch, as the author was only two months in the field, but his observations have undoubted value; doubtless a more thorough study will be made of these interesting people. The sixty-two plates which illustrate the paper add very considerably to its value, and by their means one can gain a very good idea of these jungle folk. A very useful album of Philippine types by D. Folkmar has been published by the Philippine Exposition Board, Manila; it contains eighty plates of photographs—full-face and side view of head—of inmates of Bilibid prison. The author has been careful to select typical examples from various districts, and opposite each plate are given certain measurements of the individual photographed, together with the averages of the same measurements taken on a large number of examples of that particular tribe. This is a very useful device, as it gives some sort of clue as to whether the individual figured is a fairly typical example of his tribe.

WRITING to *La Sicilia*, Prof. A. Ricco mentions that the crater of Etna is extending towards the north-west, and along the whole of the circumference, from north to west, is a great continuous fissure emitting steam and heated vapours. As the whole of the ground between this fissure and the margin must fall into the crater, he warns intending visitors of the need of caution in approaching the crater from the westwards, the direction from which it is most easily accessible.

IN the May number of the *Rend. Acc. Lincei* A. Pochettino describes the luminescence emitted by certain crystals under the action of radium and Röntgen rays.

The light given out by the platino-cyanides is, as a rule, vivid and partially polarised; it disappears directly the exciting cause is withdrawn. Crystals of scheelite, phosgenite, &c., show a feeble luminescence lasting several seconds after the removal of the incident rays.

IN part i. of a contribution to the *Scientific Transactions of the Royal Dublin Society,* vol. viii., p. 16, Prof. A. W. Conway discusses the partial differential equations of mathematical physics which in their general form are partial differential equations of the second order with constant coefficients reducible by transformation to three different classes. The problem has been attacked by Whittaker from the point of view of building up singular solutions from plane-wave solutions, but Prof. Conway adopts the reverse course, starting with the singular solution.

AMONG the results of the recent Röntgen congress at Berlin has been the authoritative adoption by a special committee of the following terminology:—Röntgenology = the study of Röntgen rays, Röntgenoscopy = observation by Röntgen rays, Röntgenography = photography by the rays, Orthoröntgenography in place of orthodiagraphy, Röntgenotherapy and the verb to röntgenise in their obvious meanings.

THE question "What is research?" is discussed by Prof. Henry S. Williams in the *Popular Science Monthly.* The author considers that research is not a special faculty possessed by the few, but a common faculty specially trained and systematically exercised by the few, for whom it becomes a tool of the highest value, and the means of opening up new fields of knowledge to mankind. At the same time, he directs attention to the detrimental effects of too much book learning on the power of research, and the need of a vivid imagination such as can be exercised and disciplined by the study of mathematics. Moreover, the man of research must be prepared to sacrifice his prospects in other directions and to work alone, "unappreciated and unapplauded" in most of his work, and Prof. Williams finally cautions teachers against tempting mere enthusiasts to undertake a task which requires for success the toughness of a soldier, the temper of a saint, and the training of a scholar. The subject of the article is one which might be very well discussed further in view of the large amount of "research," falsely so-called, which is now being turned out by persons not possessing any of these qualities, with the great danger of lowering public estimation of the importance of work of real scientific value.

DR. J. HETTINGER, writing from London in the *Physikalische Zeitschrift* for June 15, describes a new electrical connection for intensifying the resonance effects in wireless telegraphy.

THE Mathematical Association has reprinted the report of its committee on the teaching of elementary mathematics. In the same pamphlet are reproduced the "Little Go" regulations in geometry. We observe that Cambridge advocates the "hard pencil," which leads to so many indistinct figures in candidates' answers. A valuable mental training is thus omitted in not requiring candidates to make their drawings, as well as written work, clear and distinct to others. Moreover, even a soft pencil with a thick point has an advantage in showing that in any *constructive* proof lines must necessarily be of a certain thickness, and the conclusion is only established as approximately true. The beginner who learns this will be the better able to appreciate the deductive method at the proper time.

THE surfaces obtainable by the deformation of a hyperboloid of revolution of one sheet are discussed by Prof. Luigi Bianchi in the *Atti* of the Lincei Academy, xiv., 10. The determination of these surfaces is shown to depend on that of a certain class of imaginary pseudospherical surfaces, and the difficulty of the problem is reduced to that of characterising these latter surfaces, and thus presenting the final transformation formulæ in a real and definite form.

THE Institution of Electrical Engineers has published an address delivered to its students in January last by Mr. James Swinburne, M.Inst.C.E., on "The Theory of Electricity and the Value of its Study to Engineers." In it the author emphasises the desirability in many cases of mathematics being learnt through its applications, and points to the theory of electricity as affording a valuable introduction to the study of many of the most important branches of mathematical analysis. In conclusion the author says:—"I feel confident that enough has been said to make it evident that a modern engineer cannot consider his technical equipment complete without some knowledge of the theory of electricity; and if electrical development continues at the present rate it may soon be the most important branch of the science of engineering."

Biologisches Centralblatt of July 1 contains the report of an interesting address on the use and place of hypotheses, suppositions, and problems in biology, delivered by Mr. J. Reinke at the opening session of the International Botanical Congress at Vienna on June 12. That theories and hypotheses have a great and important place in science—indeed, that they are absolutely essential to its proper advance—the lecturer fully admitted; but, he added, it is necessary to remember that they are nothing more than theories, otherwise there is the greatest danger of their proving a hindrance and an illusion. A notable instance of this danger is afforded by the numerous phylogenies of animals and plants which are published from time to time, and are too often accepted as though they were solid facts, instead of being in most cases mere hypotheses, based not unfrequently on the very slenderest of foundations.

A YEAR ago we referred to notices of the occurrence of the striped hawk-moth in this country, and we observe that in the *Entomologist* for June and July several instances of the capture of the same species this season are mentioned. Possibly this handsome moth may become established in the south of England, at least for a time. In the July number Mr. G. W. Kirkaldy continues his popular synopsis of British water-bugs.

To the *Journal of Conchology* for July Mr. A. D. Darbishire contributes a discussion on Prof. Lang's experiments in breeding with the two common garden snails *Helix hortensis* and *H. nemoralis.* The writer denies that these experiments confirm the truth of Mendel's doctrine, *stricto sensu*; that is to say, they do not afford conclusive evidence of the existence in the gonads of *H. hortensis* of definite unit-bearing elements representing either five-banded or unbanded shells. It is added that much interest will attach to the description of the characters of the "dart" in the hybrid between the two species in question.

In the course of a paper published in the June number of the *American Naturalist* on the advantages presented by the common skate as a subject for demonstration to anatomical classes, Dr. H. W. Rand takes occasion to emphasise the importance of selecting generalised, in place of specialised, species for such demonstrations. A skate or a dog-fish is thus to be preferred to a bony fish, and similarly a salamander to a frog. As regards the choice between a skate and a dog-fish, although the former is a much more specialised type than the latter, it has the advantage of being more easily obtained and of being available for the greater part of the year. Moreover, its very specialisation happens to be an advantage to it as an object for demonstration, for not only does its flattened form render it admirably suited for dissection, but most of its organs are brought more or less nearly into one horizontal plane, so as to be capable of demonstration almost as if drawn in a diagram. Apropos to this article is a second, by Messrs. Rand and Ulrich, on posterior connections of the lateral vein in the skate. To the same issue Mr. E. W. Berry contributes an article on fossil sedges and grasses, with the description of a new Carex; and Mr. J. A. Cushman one on the fossil crabs from the well known Miocene beds of Gay Head, Mass., described long ago by Dr. E. Hitchcock, and subsequently by Sir C. Lyell.

An interesting paper on the gradual dissociation of mellitic acid is contributed by A. Quartaroli to the current number of the *Gazzetta Chimica Italiana*, vol. xxxv. p. 470. The author has measured the rate at which cane sugar is inverted by mellitic acid and by the corresponding mono-, di-, tri-, tetra-, and penta-sodium salts in one-tenth molecular solution. If the velocity constant for the free acid is represented by 100, the values for the various salts in the order given are respectively 40·5, 14·3, 2·2, 1·5, and 1·04. These numbers may be taken as a measure of the relative tendencies to ionisation of the six successive acid hydrogen atoms. Taking the ratio of the first to the second, of the second to the third, &c., the series 2·47, 2·82, 6·49, 1·47, 1·43 is obtained. These numbers are interesting, and the occurrence of a maximum value in the middle of the series suggests that the dissociation of mellitic acid is of abnormal character.

During the past week the Royal College of Surgeons of Edinburgh has been celebrating its four hundredth anniversary. The college, which is the oldest medical or surgical corporation in the United Kingdom, dates from July 1, 1505. The Royal College of Physicians of London, the next in point of age, was officially established some thirteen years later, *i.e.* in 1518. The current number of the *Lancet* contains an interesting account of the older institution.

The third number of the second volume of the Investigations of the Departments of Psychology and Education of the University of Colorado has reached us. Among other contributions, those in which Prof. Francis Ramaley deals with the teaching of botany and zoology, and Prof. Chas. A. Lory with the teaching of physics, are of special interest.

We have received a copy of "Southern Rhodesia, Information for Settlers," a small handbook issued by the British South Africa Company. The title sufficiently indicates the nature of the contents of the book, but it is worth noting that many of the numerous illustrations are of considerable geographical interest and value.

The report of the Royal Cornwall Polytechnic Society for 1904 has just been published, and bears testimony to the continued vitality of the society. One of the chief features of the society's activities during the year was its exhibition, in connection with which addresses and papers were given on electrical research, practical bee-keeping and management, and the geology, minerals and mines of Lelant, St. Ives, and Zennor. The first and last of these communications are to be found in the report before us, as is also an informing paper by Mr. C. C. Bignell on the aphides with their food plants; the volume likewise contains a detailed report of the work accomplished at the Falmouth Observatory.

The new number of the *Quarterly Review* contains only two papers dealing with scientific subjects, one on the national coal-supply, the other, by Sir Charles N. Eliot, on the Buddhism of Tibet. Both communications are very informative and eminently readable.

Messrs. R. and J. Beck, Ltd., of Cornhill, have just issued a catalogue of microscopes and apparatus specially suited for metallurgical work.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in August:—

Aug. 2. 1h. Mercury at greatest elongation (27° 18′ E.).
" 2. 12h. 28m. to 14h. 6m. Transit of Jupiter's Sat. III. (Ganymede).
" 4. Pallas in opposition to the sun.
" 11–13. Epoch of Perseid meteoric shower (Radiant 45° + 57°).
" 12. Saturn. Major axis of ring = 43″·82, Minor axis = 7″·47.
" 14. 10h. Venus in conjunction with Neptune, Venus 0° 48′ S.
" 14. Partial eclipse of the moon visible at Greenwich.
14h. 39m. First contact with shadow.
15h. 41m. Middle of the eclipse.
16h. 43m. Last contact with shadow.
Magnitude of eclipse = 0·292. Moon sets 16h. 53m.
" 15. 9h. Saturn in conjunction with moon, Saturn 1h. 43m. S.
" 15. Venus. Illuminated portion of disc = 0·680, of Mars = 0·854.
" 16. 11h. 49m. Minimum of Algol (β Persei).
" 19. 8h. 38m. Minimum of Algol (β Persei).
" 22. 21h. 0m. Saturn in opposition to the sun.
" 23. 12h. 5m. to 12h. 46m. Moon occults σ^2 Tauri (Mag. 4·8).
" 30. Total eclipse of the sun, partly visible at Greenwich.
11h. 49m. a.m. Beginning of the eclipse.
1h. 3m. p.m. Middle of the eclipse.
2h. 15m. p.m. End of the eclipse.
Magnitude of eclipse = 0·786. Sun's altitude at noon = 48°.

Photographs of the Martian Canals.—Since the opposition of Mars in 1901, persistent efforts have been made at the Lowell Observatory to secure photographs of the planet on which the canals could be seen definitely. After making a number of exposures with a camera in which the film was continuous, so that a large number of short exposures—as in the bioscope—could be made on the one film, Mr. Lampland succeeded in obtaining negatives which demonstrate indubitably the actual existence of the "canals" Nilosyrtis, Pyramus, Casius, Protonilus, Astaboras S., and Thoth. In addition to these, the "regions" Syrtis Major, Mare Erythræum, Mare Icarium, Hellas and the north polar cap, and the "oasis" Lucus Ismenius are plainly discernible. A photographic print from a negative secured on May 11 at 19h. 44m.–48m. (G.M.T.) on which these features are visible is affixed in the *Lowell Observatory Bulletin*, No. 21, accompanied by a drawing made by Mr. Lowell immediately before the exposure was made. Other photographs secured

show other canals, and Mr. Lampland is to be congratulated, in company with Mr. Lowell, upon thus securing unquestionable evidence of the actual existence of these features.

A point of special interest to planet observers is that whilst trying to obtain these photographs the observers found that the restriction of the aperture employed, by its elimination of the evil effects of atmospheric vibrations, more than counterbalanced the inconvenience caused by the diminution of light-gathering power and the consequent increase of the length of the exposures, a result which confirms the conclusion previously arrived at by Mr. Lowell from visual observations.

DUTCH OBSERVATIONS OF THE CORONA.—Parts iii. and iv. of Prof. Julius's report on the observations made by the Dutch expedition in Sumatra during the total solar eclipse of May 18, 1901, minutely describe the apparatus and the methods of procedure employed in examining the coronal radiations for polarisation effects and for the determination of the amount of heat radiated by the eclipsed sun.

A double-image polarimeter of the Cornu pattern, slightly modified, was employed to examine the polarisation at different points of an image of the corona. The points examined were situated at different distances from the sun's limb, and the position of each was carefully recorded. The results showed that the coronal rays were more strongly polarised at some distance from the limb than nearer to it, whilst at greater distances the polarisation again decreased. A discussion of some experiments, performed after the eclipse, on the depolarising effect of haze and clouds showed that this effect was practically negligible.

The observations of the total heat radiated by the eclipsed sun were made with a thermopile pointed directly to the corona, but clouds robbed the observations of any definite result. So far as they go, the resulting figures show that the heat radiated at totality is not so great as that received from the full moon, and that a very striking increase occurred after the third contact.

THE NORTH POLAR SNOW-CAP ON MARS, 1904-5.—Observations of the north polar cap of Mars were made at the Lowell Observatory by Messrs. Lowell and Lampland during the period November, 1904, to May, 1905, and the observers' notes for each night are given in full in No. 20 of the *Lowell Observatory Bulletins*.

One remarkable feature observed was a white collar which surrounded the cap during the latter half of January. Mr. Lowell explains this phenomenon by the conjecture that it is a belt of spring haze which surrounds the cap during the hotter months of the melting, the cap proper being bordered by a blue belt of material (probably water) produced by the melting of the snow. Several subsidiary patches of snow were left behind by the receding polar cap, and became prominent features.

Of these, one in longitude 206° was especially marked, and was recorded in exactly the same longitude by Schiaparelli in 1888, and independently at the Flagstaff Observatory in 1901 and 1903.

VEGETATION AND THE SUN-SPOT PERIOD.—Since 1871 M. Camille Flammarion has each year recorded the dates on which the chestnut trees in the avenue of the Paris Observatory have burst into leaf and flowered. Plotting the results of his observations with the sun-spot curve on the same year-scale, he found that the variation of the dates of the different phases of the annual arboreal phenomena agreed very closely with the latter curve, the leaf-buds bursting and the flowers appearing earlier at those epochs when the sun-spot *maxima* occurred. The details of the observations and the method employed in reducing them are given in the July number of the *Bulletin de la Société astronomique de France*.

VISIBILITY OF THE DARK HEMISPHERE OF VENUS.—In a paper on the influence of the solar-activity variations on the planets, M. Hansky directs attention to the greater visibility of the dark hemisphere of Venus during epochs of maximum solar activity. According to the theory of Arrhenius, electrified ions emitted by the sun cause the phenomena of terrestrial magnetic storms and auroræ. Applying the same theory in the case of Venus, M. Hansky suggests that during the periods of solar maxima the dense atmosphere of that planet is rendered more phosphorescent, and, therefore, more easily visible, by the increased solar activity. He further suggests that, in order to test this theory, astronomers should observe the planet as often as possible during the present sun-spot maximum (*Bulletin de la Société astronomique de France*, July).

DETERMINATIONS OF METEOR RADIANTS.—Some interesting results of meteor observations are recorded in No. 4032 of the *Astronomische Nachrichten* by M. Eginitis, of Athens, and by Prof. A. A. Nijland, of Utrecht.

M. Eginitis observed the Perseid, Leonid, and Andromedid showers of 1903 and the Perseid shower of 1904. He gives the time of observation, the number, colour, magnitude and relative velocity of the meteors recorded, and the position of the determined radiant on each date, directing special attention to any objects which were, for any reason, extraordinary. On August 11, 1904, several meteors were seen to proceed from a radiant near to α Persei, and these were, in general, whiter and brighter than those from η Persei, the latter being fainter and of a reddish-yellow colour, and generally falling in pairs.

Prof. Nijland's results deal with the Lyrid, Perseid, and Leonid showers of 1902, 1903, and 1904, and he gives the results for each night of observation and the positions deduced for the respective radiants.

THE INSTITUTION OF NAVAL ARCHITECTS.

THE summer meeting of the Institution of Naval Architects was held last week in London, the usual sittings for the reading of papers taking place in the theatre of the Society of Arts. The following papers were on the programme for reading and discussion:—Tactics and strategy at the time of Trafalgar, by Admiral Sir Cyprian Bridge; the ships of the Royal Navy as they existed at the time of Trafalgar, by Sir Philip Watts, Director of Naval Construction; the classification of merchant shipping, illustrated by a short history of Lloyd's Register, by H. J. Cornish, chief ship surveyor to Lloyd's Register; experiments with models of constant length and form of cross section, but with varying breadths and draughts, by Lieut.-Colonel B. Rota, Royal Italian Navy; experiments upon the effect of water on speed having special reference to destroyers recently built, by Harold Yarrow; deductions from recent and former experiments on the influence of the depth of water on speed, by W. W. Marriner; the failure of some large boiler plates, by J. T. Milton, chief engineer surveyor to Lloyd's Register; a comparison of the performances of turbines and reciprocating engines in the Midland Railway Company's steamers, by William Gray.

It was also arranged that visits should be paid to the following works:—Siemens Bros. and Co.'s Telegraph and Electrical Instrument Works, near Woolwich; Vickers, Sons and Maxim Ordnance Works, Erith; J. and E. Hall's Refrigerating Machinery Works, Dartford; Yarrow and Co.'s ship-building yard and marine engine works, Poplar; John I. Thornycroft and Co.'s ship-building yard, marine engine works, and motor-car works, Chiswick. Visits were also paid to the P. and O. mail steamer *India*, lying in the Tilbury Docks, and H.M.S. *Black Prince*, built by the Thames Iron Works, and lying in the Victoria Docks. The last day of the meeting, Friday, July 21, was occupied by a visit to Portsmouth Dockyard.

The first sitting during the meeting, when the three first papers on the list were presented, was held on Wednesday, July 19, the president of the institution, the Right Hon. the Earl of Glasgow, occupying the chair. These papers, as will be gathered by the titles, were chiefly of historical interest. In this centennial year of Trafalgar it was, no doubt, appropriate for the institution, which is so largely naval in its composition, to include in its programme papers of the nature of those contributed by Sir Cyprian Bridge and Sir Philip Watts; but how far they have any scientific bearing on naval strategy or tactics of the present day is a question that is evidently open to discussion. It would appear that a large section of naval officers hold that the lessons of the past era of masts and sails should be applied with little modification

to the present day. For example, Admiral Sir Edmund Fremantle said that the tactics and strategy at the time of Trafalgar taught lessons which would never die, and Admiral Custance remarked that all the lessons of the past in naval warfare have a bearing on the present day, it being quite immaterial whether vessels were moved by steam or sail. On the other hand, there are some who hold that the disciples of what has been described as the "teachings-of-history" school carry their reverence for the past to an excessive degree, and that a too blind following of the tactics and strategy of the great admirals of the past may lead to disaster. Sir Philip Watts, in the course of his paper, pointed out that "steam propulsion, in all its various forms, shell fire, iron and steel armour, steel hulls, breech-loading and rifled guns, torpedoes, mines, high explosives, electrical appliances, and submarines" have all been introduced since the day of Trafalgar; and though he did not press any moral from these changes, his predecessor at the Admiralty was a little more explicit, as it was possible for one no longer trammelled by the rules or etiquette of office to be. Sir William White said in the discussion that while he agreed with Sir Cyprian Bridge that the teachings of history were valuable, it was necessary to allow for changes brought about by time. He did not think such a course was followed on all occasions.

Mr. Cornish's paper, as a record of the past by a competent authority, is one which should prove of considerable value to the student and historian of ship-building. The author did not urge its reading as time was short, and it was accordingly taken as read.

Colonel Rota's paper was the first taken at the evening sitting of Wednesday, July 19. It formed but a part of a very big subject, and was in the nature of an addition to Mr. R. E. Froude's paper on model experiments, read last year. The experiments briefly described by Colonel Rota were made with five models at the Royal Italian Dockyard, Spezia. It would be difficult to give the results of the inquiry without going into the whole question, but it may be stated that the author, without attempting to draw any general deduction, has practically concluded that in the unlimited series of forms which may be derived from a given form of hull by changing the vertical and horizontal cross sections scale—provided that the area of cross sections remains constant—there is a range of ratio of beam to draught, very close to that corresponding to the least wetted surface, within the limits of which there is not any sensible variation in the value of the resistance constant, that is, the corresponding E.H.P. There was no discussion on this paper, but Sir William White had written to Mr. Dana, the secretary, endorsing the author's plea for the publication of results of a purely scientific nature.

The two papers contributed respectively by Mr. Harold Yarrow and Mr. W. W. Marriner were no doubt the chief attraction during the meeting, and the little theatre of the Society of Arts was crowded to its full capacity by those anxious to benefit by the investigations carried out by Messrs. Yarrow and Co. Both papers referred to the same experiments, the authors having been engaged together on the work. Mr. Marriner, as is well known, is the chief of Messrs. Yarrow's scientific staff, whilst Mr. Harold Yarrow is still a student of the institution, and it is worth noting that his paper is the first contribution to the *Transactions* by a student. The data given possesses the merit of being both of scientific and practical interest. It has for some time past been recognised that depth of water has a considerable influence on the speed of steam ships, and Government contractors have lost considerable sums of money through failure to attain speed on the official measured miles. The scientific interest of the subject is unlimited, the problem involving the study of the natural laws governing wave-making and fluid resistance. It is to be hoped that ship builders and ship owners—now they have had placed before them so striking an example of the value of scientific research upon the practical results at which they aim—will do something tangible to help forward an inquiry into the influence of physical laws upon the resistance of vessels progressing in water. It is not creditable to the ship owners and ship builders that they should be beholden to the generosity of a private firm of torpedo-boat builders for information on these points, especially as such information cannot be obtained without the expenditure of several hundreds of pounds. The exclusive knowledge of the facts set forth in the two papers would prove a valuable asset to Messrs. Yarrow and Co. by giving them a distinct advantage over their competitors, and it is therefore more creditable to them that they have made the details public. It is, however, the greatest reproach of all to us, as the leading maritime nation, that Mr. Yarrow should have been under obligation to a German ship-owning firm for the facilities needed to make the investigation complete. Had it not been for the hospitality of their experimental tank offered by the North German Lloyd Company, the valuable information now at the command of ship designers would not have been forthcoming, for there is no tank of the same nature in this country which could have been used.

The experiments upon which the two papers were founded arose through Messrs. Yarrow and Co. having failed to get the contract speed of 25½ knots with destroyers built for the Royal Navy when they were tried on the Maplin mile off the mouth of the Thames. The builders, anticipating that the limitation in depth of water was accountable for the want of success, surveyed on their own account a mile near Dover, the section posts being placed on the cliffs. Here, in a greater depth of water—50 feet at low tide—the contract speed was reached, the vessels running a great part of the time in quite deep water outside the Goodwins. It should be explained that the trials last over four hours, and only six runs are made on the measured mile. On these six runs is found the number of revolutions needed to cover a mile, and then by counting the revolutions the distance steamed can be known. Although the contract was fulfilled, the results were not altogether satisfactory to the contractors, and Mr. Yarrow determined to have tank experiments made, testing a model of the destroyer at depths corresponding to 20 feet, 30 feet, 45 feet, 60 feet, and 90 feet respectively. The results were shown by diagrams thrown on the screen by the lantern, there being curves for speeds and for effective horse-power at the above depths. The results were somewhat remarkable. Each curve showed a distinct hump, indicating that when a certain speed was reached the power needed for an increased speed rose with enormous rapidity. This, of course, was in accordance with previous experience, and it was also to be expected, as shown by the diagram, that the hump would occur at lower speeds with shallower water; thus at 20 feet depth the top of the hump was at about 16 knots, at 45 feet it was about 20 to 21 knots, and at 90 feet the steepest part was from 20 to 24 knots. As the depth increased the curve became fairer.

The interesting feature brought out, however, was the fact that at a certain speed, depending on the depth of water, for a time the power decreased as the speed advanced. Thus in a depth of 20 feet, at a speed of about 15¾ knots, 2000 horse-power was needed; when the speed had been increased by approximately another knot the power developed was about the same, whilst at 17½ knots the demand for power had fallen off appreciably, and it was not until 18 knots was reached that the 2000 horse-power was again required, and after this the curve rose steadily. With a depth of 30 feet the descent of the curve was even more marked, about 2500 horse-power being needed for approximately 17½ knots and for 20 knots also. Comparing the powers required for speeds at different depths, we find also some remarkable results. At 18 knots 2500 horse-power was needed when the water was 30 feet deep, whilst when it was but 20 feet only 2000 horse-power had to be developed to reach the same speed, thus reversing the popular idea that the deeper the water the easier the boat would run. Again, at 20 knots, and when the water was 20 feet (and also when the depth was about 30 feet—the two curves approximately coinciding here), 2500 horse-power was needed, but to get the same speed with a depth of 45 feet about 315 horse-power was needed. Passing at once to the higher speed of 26 knots, we find that the highest power is needed when the boat is steaming in deepest water. After crossing and re-crossing each other, the curves for four depths (20 feet, 30 feet, 45 feet, and 60 feet) come fairly well together, having got

over all the humps at about 25 knots, where there is a range of about 200 horse-power. The curve for 90 feet of water is, however, for 5000 horse-power at 26 feet, or about 500 horse-power above the next highest curve. It would therefore pay better, according to these model experiments, to run a 26-knot trial of a destroyer in a depth of 20 feet to 60 feet rather than at a depth of 90 feet; the saving in power for the given speed due to the use of shallower water would be about 600 to 700 horse-power.

We have been obliged to depart from the text of Mr. Harold Yarrow's paper in order to give the facts contained in his diagram. Limits of space prevent detailed reference to other particulars brought forward by these suggestive trials, but enough has doubtless been said to show their interest and the wide field for further investigation that is afforded by the numerical data now at command. It will be remembered, as Mr. Harold Yarrow pointed out, that the tank experiments were made in the usual way without propellers, and this would doubtless have a considerable influence on the results; but possibly a way may be found, as suggested by Sir William White, to add the propeller, and so bring the tank conditions more nearly akin to actual practice. It will be remembered that the late Mr. Froude proposed to run a propeller, worked by independent mechanism, at a speed of revolutions corresponding to that of actual practice, the model, of course, being towed by the carriage.

Mr. Marriner's investigation of the model results showed that they should, as Mr. Harold Yarrow said, "be accepted with caution." In order to check these tank data progressive trials were made with an actual destroyer on a carefully selected course off the mouth of the Thames. Four tugs were anchored to mark the course, which extended from the East Girdler buoy across the Tongue Sand to a point east of the extreme north-east point of the Tongue Spit. This gave water of depths varying between about 14 to 16 feet over the sand, and 100 to 102 feet in the Queen's Channel. The revolutions of the engines, the fore and aft inclination of the vessel, and the height of the stern wave were noted, indicator diagrams also being taken. The data thus obtained at varying mean speeds were given by means of diagrams thrown on the screen. We have not space to repeat all the records, but will take as an example the run made at a mean speed of about 22·2 knots, the steam pressure being 140 lb. In running from rather less than 50 feet depth into water of 20 feet, the revolutions increased from about 305 to more than 325; the inclination in a length of 20 feet decreased from approximately 5½ inches to 4¼ or 4½ inches; and the approximate height of the stern wave fell from 20 inches above the deck level to a little more than 10 inches below the deck level, or about 2 feet 6 inches. Naturally any increase or reduction of resistance to the vessel would be accompanied by increase or reduction in the rate of revolutions of the engine, the steam pressure being constant. Increased height of stern wave and greater inclination are also signs of increased resistance and a greater demand for horse-power.

It would be difficult to deal adequately with Mr. Marriner's paper within anything approaching the space we have at our disposal, and without the diagrams by which it was accompanied. We can only hope, therefore, to give an idea of its scope, and refer our readers to the original in the published *Transactions* of the institution. The contribution consisted of a discussion, on a scientific basis, of the results contained in the preceding paper, the size of waves made by a vessel in her passage being a measure of the power absorbed in their formation. As the height of the stern wave was seen to increase when the resistance of the ship increased abnormally, it was to be assumed that anything which tended to retard the formation of waves would reduce the loss from wave making. The author cited the work of W. Froude and his son, R. E. Froude, of Lord Kelvin, D. W. Taylor, of the United States Navy, and Prof. Horace Lamb. The formula for relation of length to speed of ordinary repeating waves in deep water was set forth, and also the more complicated equation for shallow water. The equation showing critical depth for speed and critical speed for depth was given, and the conclusion was drawn (supported by Scott Russell's equation for the solitary wave in canals) that "the wave at the critical speed changes from the repeating to something approaching the solitary type."

The author next considered the waves accompanying the vessel. Transverse waves should tend to become longer and longer for the same speed as the depth diminishes until, at the critical depth, these should be of the isolated type. In shallower water, past the critical depth, there would be no transverse wave corresponding to the critical depth. Actually as the waves became longer if they did not lengthen as rapidly as investigation would lead one to suppose they would be travelling faster than their natural speed, and must be dragged by the boat. The increased resistance on approaching humps in the curve supports this view. The isolated wave is non-repeating, and exists only under certain relations of depth to speed. After passing the critical point the transverse wave disappears, being replaced by confused water. The paper was accompanied by diagrams illustrating these points, and it was considered a fair deduction that the waves formed by a ship closely follow the laws of waves in open water. The effect of the vertical sides of a canal in diminishing the loss of energy was pointed out by the author, and the manner in which the restricted width of a tank might have a similar effect was noted. The interference of the bow-wave system on the stern-wave system was discussed, it being shown that the union of the bow and stern waves (the crests coinciding) resulted in a large resultant wave which would carry away a great deal of energy. The velocity of diverging waves is much less than the speed of the vessel, speeds attained up to the present not being high enough for waves to approach the critical speeds for the depths in which vessels usually run. Diverging waves apparently constitute the principal wave-making resistance at speeds beyond the critical combinations of depths and speeds under consideration. The final conclusions of the author were as follows:—"(1) The critical combinations of depth and speed do not depend on the size of the vessel. (2) Of these critical combinations there is, for every vessel, one more serious than the others, and where this worst combination occurs depends largely on the length of the vessel. (3) The depth to be avoided is given by the equation $d = V^2/10$, and the resistance diminishes in both greater and lesser depths. The further away from this bad depth the better, especially on the deep side."

In the course of the discussion which followed the reading of these papers, Mr. A. F. Yarrow, in conformity with a suggestion made by Sir William White, proposed, and Mr. S. W. Barnaby seconded, a resolution that the Admiralty be urged to erect a measured mile, where ample depth might be found, in proximity to Chatham and the Thames. This resolution was put to the meeting by Sir John Durston, who occupied the chair, and was carried unanimously. It was but the logical outcome of the facts brought forward. The measured mile in the Clyde at Skelmorlie has ample depth of water, and is, as Sir William White said, the only satisfactory mile for high-speed trials; a fact which, it is acknowledged, gives the ship-builders of that district a manifest advantage over those of other centres. Mr. Barnaby stated that when a destroyer built by his firm, John I. Thornycroft and Co., was tried on the Skelmorlie mile an increase of speed of 1 knot was obtained over that reached under the best conditions on the Maplin mile, whilst an increase of 3 knots was reached as compared to running on the Maplin when the state of the tide was most unfavourable. Sir William White, in a letter to the secretary, read at the meeting, heartily endorsed the suggestion of a deep-water measured mile off the Thames. He also pointed out, with great regret, that it was necessary for Messrs. Yarrow to go to Germany for their tank experiments, and trusted that the fact might furnish a fresh incentive towards the establishment of a research tank at the National Physical Laboratory.

In the discussion on the technical details of the two papers, besides those mentioned, Mr. J. H. Narbeth, of the Admiralty, Mr. R. Saxton White, Captain Jackson, R.N., Controller of the Navy, Mr. W. H. Whiting, chief constructor, and Prof. Biles took part. Generally it may be said the views expressed by the authors were not disputed, although Sir William White did not quite agree

with Mr. Marriner as to the importance the latter attached to the comparative narrowness of the tank.

On the Thursday's sitting Mr. Milton's paper on fractures in large steel boiler plates was read and briefly discussed. It gave particulars of the failures, the reasons for which could not be explained, of certain plates, and therefore were, naturally, attributed to "heat treatment." It is a term of exceeding comfort to the steel maker and the engineer alike, for the former is able to put the blame on the latter, and the latter to put the blame on the former, as no one can prove where the injudicious heat treatment occurred. The controversy is an old one, dating back, at any rate, to the days of the *Livadia's* boilers. Mr. Milton's paper is a suggestive contribution, and the facts he records may carry us some way towards a solution of the problem in the more or less distant future.

Mr. William Gray in his paper gave particulars of the performances of certain steamers fitted with Parsons' steam turbines. These were set forth in a table, which, as the author said, "treated the matter from a purely commercial standpoint." The discussion was largely of the same character.

The only remaining paper was not on the original programme, but was read at the conversazione which brought the proceedings to a conclusion on the Thursday evening. It was a contribution by Captain R. H. Bacon, R.N., entitled "Notes on the Causes of Accidents to Submarine Boats, and their Salvage." This paper, in harmony with the circumstances in which it was read, was of a popular nature, and was designed to show to the public at large that undue anxiety as to the safety of submarine boats is not warranted by the conditions under which they are employed. Dealing with the probability of water entering the hull through the hatch (the cause of four serious accidents through which these boats have foundered), the author pointed out that the fitting of another water-tight hatch at the base of the tower reduced the chance of accident in the future. The danger from grounding, he said, "was not very great," whilst the risk of the hull being crushed by the boat diving to too great depths argued the failure of the diving rudders, or too much water ballast. As to explosion through leakage of petrol, "in a properly designed system leaks should be practically non-existent." Another possible cause of explosion is due to hydrogen given off when batteries are being charged, but as this operation is carried on only when the boat is opened up for ventilation, "no danger exists." Altogether Captain Bacon's lecture was most reassuring, and it is pleasant to learn that his optimistic views are fully shared by his colleagues in the Service, both officers and men. The risk of sinking—involuntary sinking—being so small, it is of less consequence that only over a limited area near shore is it possible to recover a submarine boat once she has gone to the bottom. For this reason Captain Bacon considers it inadvisable that the Royal Navy should have a salvage plant of its own.

THE CONGRESS OF THE ROYAL INSTITUTE OF PUBLIC HEALTH.

THE congress of the Institute of Public Health, which this year was held in London under the presidency of the Marquis of Londonderry, attracted a large number of visitors, and much good work was done in the various sections which met at the Polytechnic and at King's College.

In a brief space it is impossible to deal adequately with the valuable discussions and papers read.

Sir James Crichton Browne, F.R.S., in his presidential address to the section of preventive medicine, chose as his subject the prevention of senility. It was, he declared, on the reduction of the death-rate that the potency of preventive medicine, as hitherto applied, stood forth conspicuously declared, and that the promise of its future sovereignty might be discerned. Fifty years ago the death-rate of England and Wales stood at 22·5 per 1000 persons; in 1903 it had dropped to 15·4—a fall of 7·1 per 1000, representing, on the estimated population of 1903, a saving of upwards of 223,000 lives per annum. As an exceptionally low rate of infant mortality had been maintained for two successive years, it might be hoped that the warnings uttered as regards infant hygiene, and more particularly infant feeding, were beginning to take effect.

It was, however, during the first half of life that the great fall in the death-rate had taken place. It was a remarkable fact that in men, at all ages from forty-five to seventy-five, there had been a startling rise in the death-rate, and that in women, from fifty-five upwards, it had been practically stationary. At the ages when we should have welcomed a rise in the death-rate, and at which only, in a hygienic Utopia, death ought to occur—eighty-five and upwards—it had fallen. Some of the nerve centres went on evolving until middle life, *e.g.* the hand and arm centres. He had ascertained that among certain classes of operatives in Birmingham the hand and arm centres did not reach their full maturity until about the thirtieth year. Similarly with the weavers of Bradford and the potters of Staffordshire. At about forty-five the productiveness of the manufactory hand generally began to diminish, and after that it contracted in an increasing ratio as time went on. The hand-failure of our operatives after forty-five was premature, and due to excessive wear and tear of the mechanism regulating manual movements. But there were other centres in the brain which, reaching maturity later, retained their power longer. Orators secured their greatest triumphs between forty-five and fifty-five, and it was with musical expression as with oratory.

The best antiseptic against senile decay was an active interest in human affairs, and those kept young longest who loved most. The natural evolution of our nerve centres was largely interfered with and too often arrested by unfavourable environment and deleterious habits of life or methods of work. It was a good working hypothesis that the natural life of man was one hundred, and that so far as it fell short of that it was "curtailed of fair proportion." Every man, he thought, was entitled to his century, and every woman to a century and a little more.

Dr. Francis Galton, F.R.S., in a paper on physical records, suggested that on February 29 in each leap year there should be school reunions at which there might be an opportunity for reviving early friendships, and at which, at the same time, the anthropometric and other records of the pupils might be added to.

Each old boy would be represented by an envelope stored in the school library. This would contain his anthropometric record to date, and he would be given printed forms, containing a few well considered questions—health, profession, preferments, marriage, children, and general remarks—and would be asked to forward the filled-in forms to the school.

Many papers were read on infantile mortality and on municipal milk depôts.

In the unavoidable absence of Sir William Broadbent, a discussion on sanatoria for consumptives was opened by Dr. T. N. Kelynack, physician to the Mount Vernon Hospital for Consumption. To illustrate the enormous economic waste to the community caused by pulmonary tuberculosis, Dr. Kelynack mentioned that in the metropolitan district alone 40,000 people died of the disease every year, and the monetary loss to London had been estimated at 4,000,000*l*.

The provision of adequate assistance for the consumptive poor demanded urgent attention. Sanatoria or hygienic hospitals undoubtedly secured the best conditions for the arrest and alleviation of the disease. At present we were just muddling along, with no satisfactory organisation of our resources and no rational cooperation.

A resolution was unanimously adopted urging the Government to appoint a commission to deal with the subject of the sanatorium treatment of the poor.

The presidential address in the section of chemistry and bacteriology was given by Prof. R. T. Hewlett. It was a plea for the recognition of the place of the specialist in the various departments of public health. Proper administration required a medical officer and his sanitary staff, a bacteriologist, a chemist, and an engineer, all working cordially together to a common end. For the smaller districts such a staff could be secured by grouping. Could they expect effective action if the medical officer was a

local practitioner who derived his livelihood by the goodwill of the local landlord?

Prof. Hewlett also denounced the way in which chemists were taking upon themselves the bacteriological examination of pathological material, and emphatically asserted that disease problems should be dealt with only by medical men. He also advocated that a course of biology should be obligatory for candidates for the associateship of the Institute of Chemistry taking the subject of biological chemistry.

An interesting discussion, opened by Dr. Newman, of Finsbury, was on the possibility of establishing a bacteriological standard of purity of milk. Dr. Newman suggested the following standards:—(a) not more than 24–25 degrees of total acidity at the time of sale, 1 degree being equivalent to 1 c.c. of deci-normal NaOH solution; (b) not an excess of pus or blood; (c) no *B. coli, B. enteritidis,* or *B. enteritidis sporogenes*; (d) non-virulent to guinea-pigs. All the speakers, including Dr. Allan Macfadyen, Prof. Kenwood, Dr. Savage, Colonel Firth, Mr. Revis and others, agreed that there was little possibility at present of fixing a standard, and Dr. Newman's suggestions did not obtain general acceptance.

Another discussion, on the relative efficiency of chemical and bacteriological methods for the examination of sewage effluents, was opened by Mr. Dibden and by Dr. Savage. There was a general agreement that chemical methods gave a better indication of proper purification than bacteriological ones, though, of course, bacteriological methods alone were of service in detecting species of micro-organisms.

Lieut. Nesfield, I.M.S., gave an interesting demonstration of a method devised by him for the sterilisation of drinking water during a campaign. He had found that chlorine in the proportion of 2 grams per 100 gallons acting for five minutes effectually destroyed the organisms of cholera, typhoid, and dysentery. His method consisted in carrying iron bottles of liquid chlorine, from which, by means of a valve, the requisite amount was liberated into the water. After five minutes a powder of sodium sulphite (2·2 grams) was added to the water, from which a double decomposition ensued, and the water was rendered absolutely tasteless. For the soldier on the march another method was devised, so that he could sterilise for himself a gallon of water. This consisted in adding to the vessel of water a tablet containing iodide and iodate of sodium. This resulted in the liberation of free iodine in the water, which acted in five minutes as an efficient germicide, and was then "killed," so that the water was rendered potable, by the addition of another tablet of sodium sulphite. In both processes the quantities of reagents employed are so small as to have no effect on the human economy; the methods are rapid, and the reagents, &c., portable.

ECLIPSE SHADOW BANDS.

ONE of the most peculiar appearances attending a total eclipse of the sun is that generally known as the "shadow bands." They are long dark bands, separated by white spaces, which are seen on the ground or sides of buildings just before and just after the total phase of an eclipse, moving rapidly. It is probable that they are not real bands, but are composed of dark patches which seem to the eye to make long bands. Their cause is not yet clearly known, as the observations in former eclipses are quite discordant. The undersigned is very desirous of obtaining observations of them at various stations along the line of totality, especially at places near the edge of the shadow, in order to compare with similar observations made by himself and others. The observations require no special instruments, and can be made by any careful person. Information is desired upon the following points:—(1) the direction in which the bands lie; (2) the direction in which they move; (3) the velocity with which they move; (4) the width of the bands; and (5) their distance apart. All of these are likely to be different before and after the total phase, so that two sets of observations are needed. The following suggestions are compiled from various sources.

Spread a white cloth or piece of canvas upon the ground in any convenient open space. It is well to spread *two* cloths or pieces of canvas, one to be used before, the other after, the total phase. Let each observer be furnished with several sticks, 4 feet to 6 feet long.

About three minutes before the time of totality, let the observer stand near the cloth with his back to the sun and watch the cloth intently. If bands or dark patches are seen, place one stick down in the direction in which they lie; after this is done place a second stick in the direction in which they are moving. Both of these operations should be done deliberately, not hurriedly, and the sticks left in position.

During the total phase the observer is free to enjoy the scene or make other observations, but it may be well to note if any bands can be seen during totality, as some have asserted.

At the close of totality the observer should be at the second cloth, or at another part of the single cloth (if he uses but one), and should repeat the observations made before totality, placing one stick down in the direction in which the bands lie, and another in the direction in which they move.

It will be seen that four sticks are needed for these observations. If two persons make the records, one should confine his attention to the direction in which the bands lie, the other to the direction in which they move. The bands are likely to be somewhat faint and poorly defined, so that extreme accuracy may not be possible.

The sticks should not be disturbed until after the eclipse, when their direction should be determined with as much care as possible, either by a compass or, still better, by a surveyor's theodolite if one is available. If neither compass nor theodolite is at hand, an estimate of the directions should be made.

The velocity with which the bands travel is more difficult to determine. The estimates vary from the speed of a man running to that of an express train. Several methods may be suggested:—

(1) Let two persons work together, one having a watch with the seconds marked on the face. Let him mark time by calling out each second. The number of the second is not important, but a simple sound to mark the seconds is sufficient. Let the other observer watch the bands and see how many he can count per second.

(2) With one observer marking time as before, let the second observer note how many seconds elapse while a band is passing between two objects the distance apart of which is known.

(3) Let a person run a short distance with the bands and see if he can keep up with them. If not, let him estimate how much faster the bands are moving than he can run.

(4) A mere guess at the speed is of some value.

The width of the bands and their distance apart can best be determined upon the cloths mentioned above, and it will add to the accuracy of the estimates if the cloths are divided by seams or in some other way into strips of known width. A carpenter's rule will aid the observer in making the estimates. The bands will probably be several inches wide and separated by spaces the width of which is the same or greater.

If the observer notices any other point connected with the bands, such as their colour, whether they are straight or wavy, whether they are continuous bands or made up of dark patches, whether they flicker or not, the information will be valuable. Still more valuable would be photographs of the bands as they pass over the ground or the side of a building or wall.

It is earnestly requested that anyone who will kindly attempt the above, either in whole or in part, will send his records to the undersigned. If for any reason the observation seems unsatisfactory, either because the bands were not as distinct as expected, or for any other reason, or if the record is only fragmentary, it will still be of value. The report should consist of a statement of the methods employed by the observer or observers in making the observations, and the results obtained, with any

remarks upon the subject or upon other phenomena noted at the time of the eclipse. A. LAWRENCE ROTCH.

Blue Hill Observatory, Hyde Park, Mass., U.S.A.

The observations may be summarised as follows:—

OBSERVATIONS OF SHADOW BANDS, AUGUST 30, 1905.

Place ....

(Situation and altitude)

Remarks:

Direction of the wind before totality....................., after totality....................., and direction from which upper clouds (if any) came.....................

THE LATENT IMAGE.[1]

MY inclination has led me, in spite of a lively dread of incurring a charge of presumption, to address you principally on that profound and most subtle question, the nature and mode of formation of the photographic image. I am impelled to do so, not only because the subject is full of fascination and hopefulness, but because the wide topics of photographic methods or photographic applications would be quite unfittingly handled by the president you have chosen.

I would first direct your attention to Sir James Dewar's remarkable result that the photographic plate retains considerable power of forming the latent image at temperatures approaching the absolute zero—a result which, as I submit, compels us to regard the fundamental effects progressing in the film under the stimulus of light undulations as other than those of a purely chemical nature. But few, if any, instances of chemical combination or decomposition are known at so low a temperature. Purely chemical actions cease, indeed, at far higher temperatures, fluorine being among the few bodies which still show chemical activity at the comparatively elevated temperature of $-180°$ C. In short, this result of Sir James Dewar's suggests that we must seek for the foundations of photographic action in some physical or intra-atomic effect which, as in the case of radio-activity or fluorescence, is not restricted to intervals of temperature over which active molecular *vis viva* prevails. It compels us to regard with doubt the *rôle* of oxidation or other chemical action as essential, but rather points to the view that such effects must be secondary or subsidiary. We feel, in a word, that we must turn for guidance to some purely photo-physical effect.

Here, in the first place, we naturally recall the views of Mr. Bose. This physicist would refer the formation of the image to a strain of the bromide of silver molecule under the electric force in the light wave, converting it into what might be regarded as an allotropic modification of the normal bromide which subsequently responds specially to the attack of the developer. The function of the sensitiser, according to this view, is to retard the recovery from strain. Bose obtained many suggestive parallels between the strain phenomena he was able to observe in silver and other substances under electromagnetic radiation and the behaviour of the photographic plate when subjected to long-continued exposure to light.

This theory, whatever it may have to recommend it, can hardly be regarded as offering a fundamental explanation. In the first place, we are left in the dark as to what the strain may be. It may mean many and various things. We know nothing as to the inner mechanism of its effects upon subsequent chemical actions—or at least we cannot correlate it with what is known of the physics of chemical activity. Finally, as will be seen later, it is hardly adequate to account for the varying degrees of stability which may apparently characterise the latent image. Still, there is much in Mr. Bose's work deserving of careful consideration. He has by no means exhausted the line of investigation he has originated.

Another theory has doubtless been in the minds of many. I have said we must seek guidance in some photo-physical phenomenon. There is one such which preeminently connects light and chemical phenomena through the intermediary of the effects of the former upon a component part of the atom. I refer to the phenomena of photo-electricity.

It was ascertained by Hertz and his immediate successors that light has a remarkable power of discharging negative electrification from the surface of bodies—especially from certain substances. For long no explanation of the cause of this appeared. But the electron—the ubiquitous electron—is now known with considerable certainty to be responsible. The effect of the electric force in the light wave is to direct or assist the electrons contained in the substance to escape from the surface of the body. Each electron carries away a very small charge of negative electrification. If, then, a body is originally charged negatively, it will be gradually discharged by this convective process. If it is not charged to start with, the electrons will still be liberated at the surface of the body, and this will acquire a positive charge. If the body is positively charged at first, we cannot discharge it by illumination.

It would be superfluous for me to speak here of the nature of electrons or of the various modes in which their presence may be detected. Suffice it to say, in further connection with the Hertz effect, that when projected among gaseous molecules the electron soon attaches itself to one of these. In other words, it ionises a molecule of the gas or confers its electric charge upon it. The gaseous molecule may even be itself disrupted by impact of the electron if this is moving fast enough and left bereft of an electron.

We must note that such ionisation may be regarded as conferring potential chemical properties upon the molecules of the gas and upon the substance whence the electrons are derived. Similar ionisation under electric forces enters, as we now believe, into all the chemical effects progressing in the galvanic cell, and, indeed, generally in ionised solutants.

An experiment will best illustrate the principles I wish to remind you of. A clean aluminium plate, carefully insulated by a sulphur support, is faced by a sheet of copper-wire-gauze placed a couple of centimetres away from it. The gauze is maintained at a high positive potential by this dry pile. A sensitive gold-leaf electroscope is attached to the aluminium plate, and its image thrown upon the screen. I now turn the light from this arc lamp upon the wire gauze, through which it in part passes and shines upon the aluminium plate. The electroscope at once charges up rapidly. There is a liberation of negative electrons at the surface of the aluminium; these, under the attraction of the positive body, are rapidly removed as ions, and the electroscope charges up positively.

Again, if I simply electrify negatively this aluminium plate so that the leaves of the attached electroscope diverge widely, and now expose it to the rays from the arc lamp, the charge, as you see, is very rapidly dissipated. With positive electrification of the aluminium there is no effect attendant on the illumination.

Thus from the work of Hertz and his successors we know that light, and more generally what we call actinic light, is an effective means of freeing the electron from certain substances. In short, our photographic agent, light, has the power of evoking from certain substances the electron which is so potent a factor in most, if not in all, chemical effects. I have not time here to refer to the work of Elster and Geitel whereby they have shown that this action is to be traced to the electric force in the light wave, but must turn to the probable bearing of this phenomenon on the familiar facts of photography. I assume that the experiment I have shown you is the most fundamental photographic experiment which it is now in our power to make.

[1] Address to the Photographic Convention of the United Kingdom, 1905. By J. Joly, F.R.S.

We must first ask from what substances can light liberate the electron. There are many—metals as well as non-metals and liquids. It is a very general phenomenon, and must operate widely throughout nature. But what chiefly concerns the present consideration is the fact that the haloid salts of silver are vigorously photo-electric, and, it is suggested, possess, according to Schmidt, an activity in the descending order bromide, chloride, iodide. This is, in other words, their order of activity as ionisers (under the proper conditions) when exposed to ultra-violet light. Photographers will recognise that this is also the order of their photographic sensitiveness.

Another class of bodies also concerns our subject:—the special sensitisers used by the photographer to modify the spectral distribution of sensibility of the haloid salts, *e.g.* eosine, fuchsine, cyanine. These again are electron-producers under light stimulus. Now it has been shown by Stoletow, Hallwachs, and Elster and Geitel that there is an intimate connection between photo-electric activity and the absorption of light by the substance, and, indeed, that the particular wave-lengths absorbed by the substance are those which are effective in liberating the electrons. Thus we have strong reason for believing that the vigorous photo-electric activity displayed by the special sensitisers must be dependent upon their colour absorption. You will recognise that this is just the connection between their photographic effects and their behaviour towards light.

There is yet another suggestive parallel. I referred to the observation of Sir James Dewar as to the continued sensitiveness of the photographic film at the lowest attained extremes of temperature, and drew the inference that the fundamental photographic action must be of intra-atomic nature, and not dependent upon the *vis viva* of the molecule or atom. In then seeking the origin of photographic action in photo-electric phenomena we naturally ask, Are these latter phenomena also traceable down to low temperatures? If they are, we are entitled to look upon this fact as a qualifying characteristic or as another link in the chain of evidence connecting photographic with photo-electric activity.

I have quite recently, with the aid of liquid air kindly supplied to me by Mr. Moss, and made in the laboratory of this society, tested the photo-sensibility of aluminium and also of silver bromide down to temperatures approaching that of the liquid air. The mode of observation is essentially that of Schmidt—what he terms his static method. The substance undergoing observation is, however, contained at the bottom of a thin copper tube, 5 cm. in diameter, which is immersed to a depth of about 10 cm. in liquid air. The tube is closed above by a paraffin stopper which carries a thin quartz window as well as the sulphur tubes through which the connections pass. The air within is very carefully dried by phosphorus pentoxide before the experiment. The arc light was used as source of illumination. It was found that a vigorous photo-electric effect continued in the case of the clean aluminium. In the case of the silver bromide a distinct photo-electric effect was still observed. I have not had leisure to make, as yet, any trustworthy estimate of the percentage effect at this temperature in the case of either substance. Nor have I determined the temperature accurately. The latter may be taken as roughly about $-150°$ C.

Sir James Dewar's actual measurements afforded twenty per cent. of the normal photographic effect at $-180°$ C. and ten per cent. at the temperature of $-252°.5$ C.

With this much to go upon, and the important additional fact that the electronic discharge—as from the X-ray tube or from radium—generates the latent image, I think we are fully entitled to suggest as a legitimate lead to experiment the hypothesis that the beginnings of photographic action involve an electronic discharge from the light sensitive molecule; in other words that the latent image is built up of ionised atoms or molecules the result of the photo-electric effect on the illuminated silver haloid, upon which ionised atoms the chemical effects of the developer are subsequently directed. It may be that the liberated electrons ionise molecules not directly affected, or it may be that in their liberation they disrupt complex molecules built up in the ripening of the emulsion. With the amount we have to go upon we cannot venture to particularise. It will be said that such an action must be in part of the nature of a chemical effect. This must be admitted, and, in so far as the re-arrangement of molecular fabrics is involved, the result will doubtless be controlled by temperature conditions. The facts observed by Sir James Dewar support this. But there is involved a fundamental process—the liberation of the electron by the electric force in the light wave, which is a physical effect, and which, upon the hypothesis of its reality as a factor in forming the latent image, appears to explain completely the outstanding photographic sensitiveness of the film at temperatures far below those at which chemical actions in general cease.

Again, we may assume that the electron-producing power of the special sensitiser or dye for the particular ray it absorbs is responsible, or responsible in part, for the special sensitiveness it confers upon the film. Sir Wm. Abney has shown that these sensitisers are active even if laid on as a varnish on the sensitive surface and removed before development. It must be remembered, however, that at temperatures of about $-50°$ these sensitisers lose much of their influence on the film. [See a paper by me read before the convention in 1894.]

It appears to me that on these views the curious phenomenon of recurrent reversals does not present a problem hopeless of explanation. The process of photo-ionisation constituting the latent image, where the ion is probably not immediately neutralised by chemical combination, presents features akin to the charging of a capacity—say a leyden jar. There may be a rising potential between the groups of ions until ultimately a point is attained when there is a spontaneous neutralisation. I may observe that the phenomena of reversal appear to indicate that the change upon the silver bromide molecule, whatever be its nature, is one of gradually increasing intensity, and finally attains a maximum when a return to the original condition occurs. The maximum is the point of most intense developable image. It is probable that the sensitiser—in this case the gelatin in which the bromide of silver is immersed—plays a part in the conditions of stability which are involved.

Of great interest in all our considerations and theories is the recent work of Prof. Wood on photographic reversal. The result of this work is—as I take it—to show that the stability of the latent image may be very various according to the mode of its formation. Thus it appears that the sort of latent effect which is produced by pressure or friction is the least stable of any. This may be reversed or wiped out by the application of any other known form of photographic stimulus. Thus an exposure to X-rays will obliterate it, or a very brief exposure to light. The latent image arising from X-rays is next in order of increasing stability. Light action will remove this. Third in order is a very brief light-shock or sudden flash. This cannot be reversed by any of the foregoing modes of stimulation, but a long-continued undulatory stimulus, as from lamp-light, will reverse it. Last and most stable of all is the gradually built-up configuration due to long-continued light exposure. This can only be reversed by overdoing it according to the known facts of recurrent reversal. Prof. Wood takes occasion to remark that these phenomena are in bad agreement with the strain theory of Mr. Bose. We have, in fact, but the one resource—the allotropic modification of the haloid—whereby to explain all these orders of stability. It appears to me that the elasticity of the electronic theory is greater. The state of the ionised system may be very various according as it arises from continued rhythmic effects or from unorganised shocks. The ionisation due to X-rays or to friction will probably be quite unorganised, that due to light more or less stable according to the gradual and gentle nature of the forces at work. I think we are entitled to conclude that on the whole there is nothing in Prof. Wood's beautiful experiments opposed to the photo-electric origin of photographic effects, but that they rather fall in with what might be anticipated.

When we look for further support to the views I have laid before you we are confronted with many difficulties. I have not as yet detected any electronic discharge from the film under light stimulus. This may be due to my defective experiments, or to a fact noted by Elster and Geitel concerning the photo-electric properties of gelatin.

They obtained a vigorous effect from Balmain's luminous paint, but when this was mixed in gelatin there was no external effect. Schmidt's results as to the continuance of photo-electric activity when bodies in general are dissolved in each other lead us to believe that an actual conservative property of the medium and not an effect of this on the luminous paint is here involved. This conservative effect of the gelatin may be concerned with its efficacy as a sensitiser.

In the views I have laid before you I have endeavoured to show that the recent addition to our knowledge of the electron as an entity taking part in many physical and chemical effects may be availed of, and should be kept in sight, in seeking an explanation of the mode of origin of the latent image.

GLACIAL STUDIES IN CANADA.

DR. WILLIAM H. SHERZER has published in the *Smithsonian Miscellaneous Collections* (pp. 453–496) a handsomely illustrated preliminary report entitled "Glacial Studies in the Canadian Rockies and Selkirks." The five glaciers selected are conveniently located in Alberta and British Columbia, and the line of the Canadian Pacific Railway passes near them. Observations have been made on the rate of motion of the Victoria Glacier, which is as low as about 52 feet a year, and on the lowering of its surface by ablation. The front of this glacier shows a shearing movement of one layer over another, as was tested by the pushing forward of iron spikes driven into an upper and a lower stratum. The right lateral moraine receives a certain amount of ground-moraine or subglacial material from a hanging glacier on Mount Lefroy, which breaks away in avalanches on to the main Victoria flow. This incident, which is well illustrated, serves to warn us from assuming that all subglacial material at a glacier's edge results from plucking action on the wall or floor in contact with the local ice.

A brief but useful discussion of "dirt-bands" follows, in which three types are distinguished. Layers of the glacier may vary in the percentage of foreign matter contained in them, and these stratified dirt-bands may be too thick to represent mere temporary variations in snowfall, and probably then correspond with short cycles of variation in the "activity of the glacier-making agencies." A second type of dirt-band is that described by Forbes, conspicuous at a distance, and transverse to the length of the ice-stream; the author traces this appearance to the alternation of depressions and ridges, stones and mud becoming washed into the former, and producing the dark bands, which may be bent forward in the central region as the glacier flows. The explanation given is adopted from Tyndall. The greater rapidity of motion in summer produces a crevasse, or a close-set series of crevasses, where there is a marked increase in the drop of the valley-floor. The sun melts out a depression along the line of the crevasse or crevasses, which remains although the fracture heals. In winter, owing to the slower motion, the ice adapts itself better to its inclines, and the few crevasses that are formed are not emphasised at the top by melting. Hence each dirt-band represents a summer season, and the interval a winter one. The third type of dirt-band depends on the greater resistance to melting offered by blue solid ice, as compared with the intervening layers of vesicular ice. The latter, therefore, form depressions on the melting of the mass, in which detritus gathers, as in the case of the far coarser dirt-bands of the second type. Dr. Sherzer proposes to call a band of the first type a "dirt-zone," and of the third type a "dirt-stripe." The well known blue bands are shown later to have no relation to stratification, and we are left in ignorance as to their origin.

On the lower Lefroy Glacier "ice-dykes" are noted, true mineral veins, as it were, with ice-crystals deposited on their walls and meeting from opposite sides along the central plane. These represent crevasses, which have been healed by the freezing of the water that at one time filled them.

The author's examination of the surfaces of junction of glacier-grains shows that melting opens up a network of delicate tube-like capillaries, which are here photographed —we presume on a natural scale—both before and after injection with potassium permanganate. As melting proceeds, this network disappears, apparently by a general coarsening of the hollows developed between adjacent grains.

FIG. 1.—Formation of Forbes's "dirt-bands," Deville Glacier, Selkirks. From Summit Mt. Fox, looking Eastward. Photographed by Arthur O. Wheeler, 1902. Canadian Topographic Survey.

We shall hope to hear more of the author's views on "block-moraines," since we cannot help thinking that such phenomena are far too common for the invocation of earthquake-action as a cause. The double moraine below Lough Coumshingaun, in the county of Waterford, would seem to come into this category; and in that case the jointed nature of the rocks higher up the mountain accounts for the preponderance of huge and angular blocks. The discovery of ice-cores within the steep lateral embankments of the Asulkan Glacier raises the question of such embankments in general; and here again we hope for further details. The illustrations, one of which is here reproduced, are richly varied, and are of equal value to the geographer and the geologist.

GRENVILLE A. J. COLE.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—It has been announced that the chemical fellowship at Magdalen College, to which an election will be made next term, is open to all persons who have qualified for the degree of B.A. at Oxford, and are not in the receipt of an income of more than 300*l*. per annum. The examination will begin on October 3, and will be mainly in the subjects recognised in the honour school of chemistry. Any candidate may submit any dissertations or papers written by him or any evidence of research work done by him.

THE council of the University of Liverpool has, on the recommendation of the university senate, determined to institute a university lectureship in experimental psychology.

PROF. W. H. WATKINSON, at present professor of engineering in the Glasgow and West of Scotland Technical College, has been appointed to the Harrison chair of engineering in the University of Liverpool formerly filled by Prof. Hele-Shaw, F.R.S.

THE governors of the Merchant Venturers' Technical College, Bristol, have decided to award annually to the most suitable candidate who, being a member of the college, has graduated in science at the University of London or gained a similar distinction, a research scholarship of the value of 50*l*., tenable at the college for one year. The research scholar will be required to undertake some research work either in the department of applied chemistry or in that of engineering. The governors will defray the cost of the apparatus and materials needed for the prosecution of such work.

THE detailed regulations and syllabus for the preliminary examination for the certificate, which will in 1907 take the place of the King's scholarship examination, which pupil teachers have been in the habit of taking at the end of their apprenticeship, have been issued as an appendix to the regulations for the instruction and training of pupil teachers, 1905. The distribution of subjects in the re-cast examination has received the careful consideration of the Board of Education. In order to be successful a candidate must pass a test in the important subjects, including composition and arithmetic, which form part i. of the examination, and also show a reasonable degree of proficiency in English, history, and geography. To quote the circular which has been distributed to local education authorities, training colleges, and pupil teacher centres:—"To these the Board would gladly have added elementary science. They have, however, refrained at present from doing so because, except in fully equipped secondary schools and pupil teacher centres, it is not always possible for candidates to obtain the necessary instruction in practical scientific work, while they are convinced that instruction in science which does not include practical work is of very little value." It is satisfactory to record this frank admission by the Board of Education of the great importance of including elementary science in every scheme of education, whether elementary or secondary. It is to be hoped that every effort will be made by the Board to bring about increased facilities for instruction in elementary science in all schools under their jurisdiction, and not only in those from which pupil teachers proceed to the training college. It is not too much to say that no system of training designed to provide efficient elementary school teachers will prove thoroughly satisfactory which does not subject the teacher in training to a course of practical work in science. Even if it is considered necessary at present to make science an optional subject in this preliminary examination for the certificate, every effort should be made so to improve the equipment of the schools that elementary science may be made obligatory for all candidates at an early date.

A TREASURY Minute upon the recommendations of the university colleges committee has been issued as a Parliamentary paper. The consideration of the final report of Mr. Haldane's committee on the allocation of the grant in aid to university colleges is resumed. The recommendation of the establishment of a permanent committee to advise the Board of Treasury as to the distribution of the grant in aid is accepted, and an endeavour will be made in the autumn to constitute such a body, which will perform the duties hitherto undertaken by the quinquennial committee of inspection. Some of the colleges have pointed out that the intervention of such a committee may interfere unduly with their internal administration, but the Minute lays it down that the main functions of the committee will be to advise the Board of Treasury as to the kind of education which should be assisted out of the grant, and to satisfy themselves by inspection that the money is being properly applied. These objects can be obtained without any undue interference with the responsibility of the college authorities. Ninety per cent. of the grant is in the future to be allocated on the same general principles as have been adopted hitherto, and such sums as may be given will be secured to the colleges for at least five years. The balance of the grant will be reserved partly for special grants towards the provision of books and apparatus and partly for the encouragement of post-graduate work. The colleges will be expected to make proposals to the advisory committee as regards post-graduate work, showing the nature of the work it is desired to undertake and the assistance the college itself intends to contribute to the work. Parliament is being asked to vote 100,000*l*. for university colleges, and if this is agreed to 89,000*l*. will be distributed and 11,000*l*. reserved for allocation in March next. The amount allotted to each college for the year 1905–6 will be as follows:—Manchester, 12,000*l*.; University College, London, 10,000*l*.; Liverpool, 10,000*l*.; Birmingham, 9000*l*.; Leeds, 8000*l*.; King's College, London, 7800*l*.; Newcastle-on-Tyne, 6000*l*.; Nottingham, 5800*l*.; Sheffield, 4600*l*.; Bedford College, London, 4000*l*.; Bristol, 4000*l*.; Reading, 3400*l*.; Southampton, 3400*l*.; Dundee, 1000*l*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 9.—"Explosions of Mixtures of Coal-Gas and Air in a Closed Vessel." By L. **Bairstow** and A. D. **Alexander.**

Summary.

Mixtures of coal-gas and air are not inflammable until the volume of coal-gas is greater than one-seventeenth of the combined volumes. Only a very small fraction of the gas then burns, the amount burnt rapidly increasing with increased richness of the mixture until the coal-gas is one-twelfth of the total volume. The least inflammable of the constituents then burns, and combustion becomes and remains complete so long as air is in excess. In these latter cases it is still probable that the constituents burn successively and not simultaneously.

The hypothesis of a specific heat increasing with temperature is not supported by direct experiment, and cannot be proved by any work on the pressures produced by explosion, the authors believing that a proof would require the measurement of temperature.

Direct experiments by Deville at temperatures below 1400° C. have shown that both steam and carbon dioxide are partially decomposed, and this dissociation is therefore taken by us as the sole explanation of the difference between the pressures calculated for explosions in a closed vessel and those actually obtained.

PARIS.

Academy of Sciences, July 17.—M. Troost in the chair.—On a new method of direct determination of refraction at all heights: M. **Lœwy.** The author describes and explains the theory of his new method by which atmospheric refraction can be measured by the use of a prism the refracting faces of which are at an angle of 45°.—On an apparatus for producing artificial eclipses of the sun: Ch. **André.** By the use of such apparatus many theoretical points can be determined in a way not otherwise possible.—On the infinitesimal properties of non-Eucildean space: C. **Guichard.**—On the distribution of sugary substances in blood between the plasma and the corpuscles: R. **Lépine** and M. **Boulud.** By eliminating certain errors due to glycolysis, the authors find for the corpuscles 22 per cent., and for the serum barely 4 per cent. of sugar.—On the evaluation of errors in the approximate integration

of differential equations: Émile **Cotton.**—A contribution to the study of liquid dielectrics: P. Gourée **de Villemontée.** The author's experiments were made with reference to the influence of the duration of charge, and the electric state of the mass after discharge. The results show that the propagation of electric charges across petrol and paraffin is comparable with that observed in crystalline dielectrics.—Experimental researches on the effect of membranes in liquid chains: M. **Chanoz.** The electromotive force developed by the chain of the general nature $MR|H_2O|MR$ depends for sign and intensity upon the nature of the membrane, the nature and concentration of the salt solution MR, and the relative position of the membranes to the liquids.—On fluorescence: C. **Camichel.** Further experiments on the coefficient of absorption in uranium glass when fluorescence is excited.—On the velocity of crystallisation from supersaturated solutions: Charles **Leenhardt.**—On the preparation of binary compounds of metals by means of heating with aluminium: C. **Matignon** and R. **Trannoy.** The great reducing power of aluminium has been utilised to prepare a considerable number of metallic phosphides, arsenides, silicides, and borides.—On the reduction of thorium oxide by amorphous boron, and the preparation of two borides of thorium: Binet **du Jassonneux.**—On the action of chloroacetic esters on the halogen magnesium derivatives of orthotoluidine: F. **Bodroux.**—On the action of ethylamine and *iso*butylamine on cæsium: E. **Rengade.** When ethylamine is condensed on perfectly pure cæsium a blue colour appears in the liquid which does not occur with sodium or calcium. In time the metal becomes a mercury-like substance which evolves gas readily, and is considered by the author to be cæsium-ethyl-ammonium.—Attempts at reduction in the dinitro-diphenyl-methane series of compounds: H. **Duval.**—On the condensation of chloral with aromatic hydrocarbons under the influence of aluminium chloride: Adolphe **Dinesmann.** By the action of chloral on benzene the author obtains in the given conditions excellent yields of trichloro-methyl-phenyl-carbinol,

$$C_6H_5—CHOH—CCl_3.$$

A similar condensation takes place with toluene, paraxylene, and anisol.—On 3:3-dimethyl-butyro-lactone: G. **Blanc.**—On the action of acetylene tetrabromide and aluminium chloride on toluene: James **Lavaux.**—On gentio-picrine: Georges **Tanret.**—On coffees without caffeine: Gabriel **Bertrand.** *Coffea Humblotiana* is noteworthy as containing barely a trace of the alkaloid.—On the development of green plants in light, in the complete absence of carbon dioxide, and in an artificial soil containing amides: Jules **Lefèvre.** The presence of the amides enabled plants to find the carbon necessary for the synthesis of both protoplasm and tissues.—On two cases of grafting (*Ipomea purpurea* with *Quamoclit coccinea* and *Helianthus multiflorus* with *Helianthus annuus*): Lucien **Daniel.**—On the disinfectant properties of smokes; attempts at disinfection with the vapour evolved from burning sugar: A. **Trillat.**—On the identification of the skin of the American admiral Paul Jones, 113 years after his death: MM. **Capitan** and **Papillault.**—On the multiple affinities of the Hoplophoridæ: H. **Coutière.**—On a new exploration of the abyss of the Trou-de-Souci: E. A. **Martel.**—On the mineral constituents of the water supplying Paris: L. **Cayeux.**—The hailstorm of July 16: A. **Berget.** Hailstones were found to weigh as much as 70 grams.

NEW SOUTH WALES.

Linnean Society, May 31.—Mr. T. Steel, president, in the chair.—Notes on the Eucalypts of the Blue Mountains, N.S.W.: J. H. **Maiden** and R. H. **Cambage.** The authors enumerate twenty-seven species and one variety collected by them. One of these, for which they propose the name of *E. Moorei*, is new; it has hitherto been looked upon as a narrow-leaved variety of *E. stellulata*, Sieb., but the juvenile foliage, for example, is very different. The past year was a specially favourable season for natural seedlings of the above genus, and a number of them are described for the first time. Particular notice is devoted to the Blue Mountain form of *E. capitellata*, Sm. Attention is directed to three plants which cannot, in strictness, be referred to any existing species, and which are looked upon as possible hybrids. The Blue Mountains, with their ready accessibility to both plateaux and valleys, considerable range in elevation, and rich Eucalyptus flora, afford special facilities for a study of the genus.—Notes on the native flora of New South Wales, part iii.: R. H. **Cambage.** This paper refers to the flora of the country between Orange, Dubbo, and Gilgandra, and directs attention to the great change that takes place from climatic causes which are regulated by the change in altitude, the fall in the country from Orange to Gilgandra amounting to about 2000 feet. Although much of the true interior flora is to be found at the latter place, it is noted that a number of plants which are typical of the coastal vegetation are also growing there, and the reason may be traced to the fact that a large sandstone area, chiefly Triassic, extends from Sydney across the Blue Mountains, continuing in broken remnants past Gulgong towards Dubbo and Gilgandra; and many of those plants which are able to withstand the cold of the higher levels cross the mountains and continue on the similar geological formation out towards the western plains. Reference is also made to an interesting species of Acacia, known locally as Motherumbung, and having affinities with *A. Gnidium*, Benth., but which in the absence of full material has not yet been identified.—Descriptions of new species of Australian Coleoptera: H. J. **Carter.** Fourteen species are described as new. These are referable to three families and eight genera, namely:—fam. Tenebrionidæ, Pterohelæus, Encara, Menephilus, Otrintus, Adelium (five species), and Coripera (two species); fam. Œdemeridæ, Pseudolychus (two species); fam. Pediliidæ, Egestria.

THURSDAY, AUGUST 3, 1905.

RECENT FRENCH MATHEMATICAL WORKS.

La Philosophie naturelle intégrale et les Rudiments des Sciences exactes. By Dr. A. Rist. Part i. Pp. vi+132. (Paris: A. Hermann, 1904.) Price 3.50 francs.

Étude sur le Développement des Méthodes géométriques. By Gaston Darboux. Pp. 34. (Paris: Gauthier-Villars, 1904.) Price 1.50 francs.

Sur le Développement de l'Analyse et ses Rapports avec diverses Sciences. By Émile Picard. Pp. 168. (Paris: Gauthier-Villars, 1905.) Price 3.50 francs.

Introduction à la Géométrie générale. By Georges Lechalas. Pp. ix+65. (Paris: Gauthier-Villars, 1904.) Price 1.50 francs.

Introduction à la Théorie des Fonctions d'une Variable. By Jules Tannery. Vol. i. Second edition. Pp. ix+422. (Paris: A. Hermann, 1904.)

Correspondance d'Hermite et de Stieltjes. Edited by B. Baillaud and H. Bourget. Vol. i. Pp. xxi+477. (Paris: Gauthier-Villars, 1905.) Price 16 francs.

THE part which France has played in the development of modern mathematical methods, especially in connection with geometry and analysis, is well known to every mathematician. Of recent years, however, the trend of mathematical thought has considerably changed in every country, and while France has produced a large school of writers on the philosophy of mathematics, it is in the opinion of the present reviewer doubtful whether this school can forge more than a very small link in the chain of mathematical development. The doubts which arose in the minds of mathematicians regarding Euclid's eleventh axiom led to the new science of non-Euclidean geometry, but it was not so much the mere philosophical speculations concerning the axiom itself as the examination of the consequences of making alternative assumptions that led to substantial progress being made. The discovery that we cannot be sure that two and two make four except as the result of experience is undoubtedly of importance, but it is in the development of the consequences of a more extended hypothesis, of which this one is or is not a particular case, that substantial progress must be sought.

Dr. Rist's book may be taken as affording a good example of the kind of philosophical speculations which arise when we try to analyse the why and wherefore of the various processes and operations occurring in even so elementary a subject as arithmetic. It contains chapters on the prolegomena of both geometry and arithmetic, but it is in connection with the latter subject that the discussion is most extended. The mere act of *counting* forms the subject of a number of paragraphs of which the general character may be fairly understood from an enunciation of the headings:—"The number considered as the result of an act," "What do we count?" "Why do we count?" "The different modes of counting." From counting the author proceeds to *calculation,* and in the following chapter gives a detailed discussion of the various processes and symbols involved in the two operations of addition and subtraction. One would naturally expect multiplication and division to be treated in the same way, but instead, Dr. Rist sets out an alternative method of approaching this study, and this first volume closes with a chapter showing how numbers serve for evaluations.

The book seems to appeal more particularly to elementary teachers who only possess a rudimentary training in algebra and geometry, for there is little or nothing in it which assumes more than an elementary knowledge of these subjects. The highly trained mathematician would hardly benefit by reading such a book, as he would probably have already formed ideas of his own on the subject, and in all likelihood would consider the treatment to be unsatisfactory in a good many respects.

Of the useful purpose that can be served by popular addresses containing the survey of wide regions of mathematical thought we have two excellent examples before us. America, with that spirit of internationalism the absence of which from our islands is so greatly to be regretted, loses no chance of picking the brains of the world's greatest mathematicians, irrespective of nationality. Prof. Darboux's pamphlet and the second part of Prof. Picard's contain the substance of addresses delivered at St. Louis last year. The two addresses are to a great extent complementary. Prof. Darboux treats of the development of geometry during the nineteenth century, and Prof. Picard gives a historical account, similar in character, of the development of analysis, with especial reference to its relations with geometry, mechanics, and mathematical physics. Prof. Picard's St. Louis address also forms a sequel to the series of three lectures delivered by him in 1899 at Clark University which form the first part of the same book. The first of these deals with the gradual extension of the meaning attached to the word "function" during the last century, and the numerous new regions of mathematical thought opened up by this development. The second deals with the theory of differential equations, and the third with analytic and certain other functions. In concluding, M. Picard advises students not to specialise in mathematics at too early a stage, but to endeavour to form a general survey of different branches of the science first, and his lectures afford an excellent preliminary step towards the formation of such a survey in the case of analysis.

An English translation of M. Darboux's addresses has appeared in recent numbers of the *Mathematical Gazette.*

M. Lechalas's small volume in the series of "Actualités scientifiques" deals with Euclidean and non-Euclidean geometry. The subject is introduced by a chapter on Euclidean geometry of one, two, and three dimensions. The geometry of Riemann's space is deduced from the Euclidean geometry of four dimensions. That the properties of a Riemann plane and a Euclidean sphere are identical so long as only

the surface itself is concerned is admitted, but whether the Riemann space is identical with, or only analogous to, spherical space in a hyperspace of four dimensions remains a subject of controversy between the author of the book and M. Mansion. At any rate, M. Lechalas does not discuss space of positive curvature independently of its connection with four-dimensional Euclidean space, and accordingly the book contains only one more chapter devoted to the geometry of Lobatchefsky and Bolyaï. In this respect the treatment is analogous to that given in some books on conics where the properties of the ellipse are proved by three-dimensional methods (orthogonal projection) and those of the hyperbola by plane geometry. Whether this is the best plan is open to question; many mathematicians seem to prefer it, and an author cannot please everybody.

In his preface, which is printed in *italics*, M. Tannery fairly well defines the scope and object of his book. Although this is a second edition, it has been entirely re-written. It is primarily intended for readers who do not possess a very extended knowledge of mathematics. It covers mainly those portions of analysis which are commonly found in English text-books on higher algebra, viz. properties of irrational numbers, continued fractions, aggregates, convergency and divergency of series and of infinite products, the binomial theorem, the exponential and logarithmic series, and expansions of trigonometric functions treated without the aid of imaginaries. Finally, we have a chapter on derived functions containing applications of the formula

$$f(x+h)-f(x)=hf'(x+\theta h),$$

and an illustration of functions which have no differential coefficient. The subject-matter may all be included under the heading "functions of real variables treated algebraically," as M. Tannery has avoided the use of geometrical methods in the present volume. A second volume is promised dealing with functions of complex variables, in which geometrical methods are to be freely used.

The treatment is clear and full, and the book gives the impression of being as good an exposition of the subject as could well be written on the lines laid down by the author. It does not profess to give historical or bibliographical information, for which the reader is referred to the "Mathematical Encyclopædia," of which the French edition is now coming out.

An interesting insight into the thoughts of two eminent mathematicians is afforded by the first volume of correspondence between Hermite and Stieltjes, covering the period 1882–1889. The intimacy seems to have arisen in 1882, out of a letter addressed by Stieltjes to Hermite dealing with a theorem of M. Tisserand relating to the expansion of the disturbing force when the mutual inclination of two orbits is considerable. The subject-matter of this letter (which is missing from the collection) was published in the *Comptes rendus* for November 13, 1882.

At this time Thomas Jean Stieltjes was attached to the Observatory of Leyden, and the influence of Hermite doubtless accounts in large measure for his activity in mathematical research during the years which followed, culminating in his migration to France in 1885, after his failure to obtain a mathematical chair in his own country.

A noteworthy feature of Stieltjes's work is his partiality for simple arithmetical tests of general theorems. The value of his examinations of numerical details must have been enormous to a man of Hermite's calibre. It seems as if Hermite in many cases furnished the ideas which Stieltjes elaborated and extended. It was not with Stieltjes alone that Hermite carried on an extensive correspondence, for he was evidently fond of writing letters, and even many of his contributions to journals appeared in epistolary form. But among his various correspondents Stieltjes played a prominent part, and it was Hermite's own wish that the letters of his colleague should be published after the premature death of the latter in 1894. One thing is unfortunately wanting. Hermite was to have written an introduction, but he did not live to do so. In its place we have a preface by M. Picard and a biographical notice by M. H. Bourget, who, in conjunction with M. Baillaud, were colleagues of Stieltjes in the University of Toulouse from 1886 until his death, and who have jointly edited the present volume.

It would be difficult to give a general summary of the subject-matter of this correspondence, which deals with continued fractions, hypergeometric series, Legendre's functions, semi-convergent series, and, indeed, analysis generally. Portraits of Hermite and Stieltjes complete the volume. There is a certain brightness and freshness about the way one of the two mathematicians writes to the other announcing some new result and the second takes up the clue and develops it, and one can imagine the delight that the two kindred spirits must have had in working together.

While the volumes before us are widely different in character, it may be well to warn the busy reader, as has been done on previous occasions, that they all possess one objectionable feature in common. While the guillotine was originally invented in France, the modern instrument of that name has not been applied to its proper use on the pages of any one of the series, consequently readers, unless they are prepared to set up a private guillotine, are compelled to waste hours in hacking and jagging the leaves with a paper knife, producing a very untidy result.

G. H. B.

THE MUTATION THEORY OF THE ORIGIN OF SPECIES.

Species and Varieties: their Origin by Mutation. By Hugo de Vries. Edited by D. T. MacDougal. Pp. xviii+847. (London: Kegan Paul and Co., Ltd., 1905.)

AT the present time, when naturalists are beginning to turn again to the problem of the origin of species, this account of Prof. de Vries's theories and experiments is sure of a welcome, partly

as the most recent exposition of that naturalist's views and researches, and partly as the first account of them available in the English language.

It has been maintained by those who attack biological problems by methods by which they insist that they do not hope to account for anything, that it is idle to attempt to explain the phenomena of variation and heredity until they have been adequately described; and although it is certain that the danger of a too premature attempt to account for things is greater among those who use methods by which they believe the fundamental nature of the things will ultimately be revealed than it is among statistical evolutionists, it does not follow that it is better to adopt the second course on account of these (really not very dangerous) pitfalls in the first. Of the possibility of adopting it without falling into them at all Prof. de Vries's work is a rare example. The book before us consists of twenty-eight lectures delivered at the California University by Prof. de Vries, and prepared for the press by Mr. D. T. MacDougal. It will be of immense value to the student whose lack of knowledge of German renders "Die Mutationstheorie" a sealed book to him, as well as to the investigator; but two features of it, which result from the mode of its origin, render it a less valuable work than "Die Mutationstheorie." One of them, which affects the student and general reader, is the absence of illustrations; the other, which affects the investigator, is the absence of references, which is a real drawback in a book that puts into circulation the details of many unfamiliar and interesting breeding experiments.

Seeing that this book is likely, and intended, to appeal to the student, there is one feature of it which might have been different with advantage; and we believe the defect to be serious, because the general reader will notice it as little as he will deplore the absence of pictures much.

The publication of a book in which there is set forth for the student a new and profoundly important biological theory, and a collection of facts in support of it, seems to us to have been a most suitable opportunity for discarding that scientific jargon which is still believed to have a meaning by those who do not understand it, and still used by those who know that it means nothing. In the very first sentence it appears in its old vigour.

"Newton convinced his contemporaries that natural laws rule the whole universe. Lyell showed, by his principle of slow and gradual evolution, that natural laws have reigned since the beginning of time."

Of course Prof. de Vries and Mr. MacDougal know that natural laws do not really rule the universe, and that they have not reigned since the beginning of time, and that this latter expression stretches even poetical licence. But the general reader and student do not know this, and when they see this kind of statement scattered through scientific literature they can be pardoned for going away with the idea that there must be laws existing somewhere ruling and reigning and being obeyed, and that it is the business of the man of science to discover them.

A few examples from the body of the book will suffice. For instance, on p. 3, "If an origin by natural laws is conceded for the latter, it must, on this ground, be granted to the first also"; on p. 90, ". . . wild species, which obey the laws discussed in a previous lecture"; on p. 175, ". . . and liable to reversions by the ordinary laws of the splitting up of hybrids"; and on p. 547, "The physiological laws, however, which govern this process are only very imperfectly revealed by such a study."

We are perfectly aware that such expressions are continually to be found in the memoirs of men of science who in their other writings have exposed the meaninglessness of such phrases; but this only leads to the necessity of a stronger insistence on the desirableness of discarding them, in the conviction that the curious image of nature which such expressions call up would be less erroneous and more eradicable than it is now if they were never used.

The fact that entirely different things sometimes have the same name leads to the need for caution in the interpretation of another expression the meanings of which are about as numerous and as different as those of the term "law." The word regression in Prof. de Vries's book denotes a biological phenomenon of singular interest; but it must not be forgotten that it is also the name of a purely statistical conception. It is very necessary that these two significations should be kept absolutely distinct in the mind of the reader.

The book is, considering its bulk, very free from misprints; the few that occur do not lead to any difficulty, *e.g.* "begining" on p. 118, "hnudred" on p. 475, "of" for "on" in the last line of p. 560. There is one inconsistency of spelling; Macfarlane is spelt thus on pp. 21 and 268, and with a capital F on p. 255. We have some doubt as to which is the more correct, "morphologic" or "morphological," though we have none as to which is the more euphonious; but surely one or the other should be used throughout; yet on p. 141 we find "morphological" and on p. 144 "morphologic," and similarly on p. 144 "physiologic" and on p. 547 "physiological," on p. 709 "empiric" and on p. 733 "empirical."

We think that scant justice is done to the greatness of Mendel's work and to the conceptions based upon it which bid fair to put us on the track of accounting for some of the phenomena of heredity; and by confining Mendel's law to the description of the mutual properties of varieties only, the meaning and tendency of Mendelian investigation that is now being carried on seem to be missed. That Hurst can predict the difference between the result of mating two pairs of rabbits externally identical, by means of a knowledge of the difference between their gametic constitutions acquired by previous breeding from them, constitutes, it seems to us, the longest stride the study of heredity has made for some time past.

The zoologist who confines himself as strictly to the study of animals as Prof. de Vries does to that of plants will be disappointed if, trusting to the comprehensiveness of the title of the book, he expects to

find as much about the one half of living nature as about the other in it.

The most fruitful source of progress is a new way of looking at things, and such new points of view result in the destruction of old classifications and the need for new ones; in biology, investigators will soon cease to be classified according to the group of animals or plants with which they deal, but according to the particular phase of the problem of the "fundamental nature of living things" (which is the ultimate goal of biological inquiry) which interests them. In the study of heredity, for example, there is already a number of investigators who are as familiar with that phenomenon in the case of animals as in the case of plants. Nor does it seem reasonable to doubt that, by thus broadening the basis of material used by the investigator, the conclusions arrived at by him are likely to be less wide of the truth than they are apt to be if they are based on the result of experiment with a single animal or plant. The moral of this is, not that Prof. de Vries ought to have said something about animals in his book, but that the disappointed zoological reader ought to know something about plants for the sake of his work.

To bestow praise on any work of Prof. de Vries would be impertinent; to cite points of particular interest in the book is unnecessary, for it has already begun to form part of the indispensable equipment of the student of evolution in the broadest sense of that term. A. D.

ASPHALT PAVEMENTS.

The Modern Asphalt Pavement. By Clifford Richardson. Pp. vii+580. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1905.) Price 12*s.* 6*d.* net.

THIS is a book dealing with an important practical subject which up to the present time has not received much attention from writers of text-books. Asphalt pavements of various kinds are now so largely used that a text-book dealing with this subject has been a long-felt want.

The book is divided into sections, and the author has appended to the end of each chapter a brief summary of the matter dealt with, enabling the reader to determine quickly whether or not the chapter contains the information he is seeking for. The first section deals with the construction of the road base upon which the surface carrying the traffic is supported, and it is evident that Mr. Richardson is of opinion that the ideal base is hydraulic concrete. Between this base and the surface proper is interposed a binder, or intermediate, course; where the traffic is heavy, the best material for this is a layer of compact asphaltic concrete. The next section is concerned with the materials employed in making the asphalt surface mixture, and a detailed account is given of the sands used for this purpose and of their origin and physical characteristics. After a brief explanation and classification of the various hydrocarbons of which native bitumen is composed, the author describes the native bitumens which have so far been used in paving work.

In section iv. the technology of the paving industry is taken up; the preparation of the surface mixture is explained with the help of elaborate tables, and the theory which underlies the practical work is described; the author points out that an asphalt surface in order to be successful must resist both weathering and impact. The mechanical appliances used for combining the various materials into the surface mixture are described with diagrams.

Sections v. and vi. deal with the handling of the material in the street and with the hand-tools needed by the workmen, and in the latter section a description of an ingenious machine for impact tests is given. In section vii. there is a complete specification for an asphalt pavement; this will be found of great value to engineers who have to draw up specifications for work of this nature. Mr. Richardson points out that the popular idea as to the limiting gradient for an asphalt pavement is erroneous, and that in the eastern part of the United States, for example, a gradient of 8 per cent. on an asphalt road is not excessive. There is no doubt that asphalt has great advantages when compared with most of the other pavement materials; it is free from mud if properly washed down at regular intervals; unlike wood, it is practically non-absorbent; when kept in a clean condition it gives a good foothold for horses; tractive effort is considerably reduced, and even under heavy traffic asphalt wears remarkably well. Although the initial cost is heavy, still the cost of upkeep is lower than that for most of the other paving materials. The last section of the book, one of the most valuable, deals with the testing of the various materials used in asphalt pavement work; it gives a complete account of this necessary branch of the work, and data are given of the equipment required in a municipal laboratory where such testing work is carried out.

The book is likely to prove of great value to municipal authorities who are faced with the problem of determining the most satisfactory road material to employ both where traffic is heavy and where it is moderate. T. H. B.

OUR BOOK SHELF.

Die physikalischen Eigenschaften der Seen. By Dr. Otto Freiherr von und zu Aufsess. Pp. x+120. (Brunswick: Vieweg and Son, 1905.) Price 3 marks.

THERE are many books and pamphlets dealing with one or several of the properties of lakes; the aim, however, of the present work is to gather into a handbook the principal facts known, and to give a general view of the results arrived at, so as to incite the lover of nature to interesting observations as well as to provide a guide for the more specialised limnologist.

In a short introduction the author deals with Prof. Forel's work as having caused the important development of limnology which recent years have witnessed, and gives this authority's definition of a lake as being "a mass of still water, closed up on all sides, situated in a depression of the ground, without direct communication with the sea." The lake surface being a part of the earth surface represents a section of a sphere, the curvature of the same being, with large

lakes, important enough to prevent the observer from seeing low objects situated on the opposite shore.

Some preliminary remarks deal with general considerations on pressure, density, and compressibility of the water. The mechanical part includes the study of the different movements to be observed in lakes, viz. progressive waves, such as are known to everybody, stationary waves or "seiches," and currents. "Seiches" were first rationally studied by Prof. Forel in the Lake of Geneva, and have been found to exist in many other lakes; they are, for instance, now being investigated in the lochs of Scotland by the Lake Survey. Being waves as long as the lake, they cause periodical rising and falling of the water-level, though these tides are very often inconspicuous, and only to be recorded by limnimeters or registering apparatus; they vary from some millimetres up to 1.87m. (highest "seiche" in the Lake of Geneva), and much more in the great lakes of America. This special kind of wave, which affects the whole body of the lake, is probably due to several factors acting together or separately, such as sudden variation of atmospheric pressure, changes in the strength or direction of the wind, &c. Older explanations, as lunar attraction or earthquakes, have been shown to be untenable as general causes of "seiches."

The acoustic properties of lakes are dealt with in a short chapter. The most attractive feature of any lake is its colour, its greater or less transparency, its reflection of the surroundings, and other optical phenomena, such as refraction in or above the water. The explanation, however, of all these facts, which anybody may observe and enjoy, is often difficult and intricate even to men of science. The author of the present work has the merit of dealing with this optical chapter in a very intelligible and attractive way, giving briefly the most accredited theories of the phenomena treated of.

The last chapter deals with the thermic properties of lakes, such as distribution of temperature, seasonal changes, formation of ice, and storage of the summer's heat by the water.

A bibliographical list of the most recent and important works on physical limnology concludes the book, and makes of it a very useful guide and an excellent *résumé* of the actual state of our knowledge of this subject.

A Catalogue of North American Diptera or Two-winged Flies. By J. M. Aldrich. (Smithsonian Miscellaneous Collections, part of vol. xlvi.) Pp. 680. (City of Washington, 1905.)

THE second edition of Osten-Sacken's "Catalogue of North American Diptera" was published in 1878, and an enormous amount of work in the order has naturally been accomplished since. Prof. Aldrich's catalogue takes in the whole of North America, from Panama on the south to Greenland and the Aleutian Islands on the north; and also the whole of the West Indies, even down to Trinidad, adjoining Venezuela. "There is no place to draw a line between the islands. The Bermudas and the Hawaiian Islands are not included."

According to our own knowledge of other orders, we cannot quite agree with Prof. Aldrich. The fauna of Trinidad appears to us to have no relation to that of the islands further north, and to be purely South American, while the Bermudas clearly belong to North America. On the other hand, that of the Hawaiian Islands (apart from introduced species) is one of the most insular in the world; and, in this respect, may be compared with that of New Zealand, though far less conspicuous or extensive.

Prof. Aldrich has not numbered or mentioned the number of species admitted in his catalogue (which is brought down to January 1, 1904); but we may say that the introduction occupies 4 pages, the system of classification 1, the bibliography (with additions) 77, the index of (59) families 1, and the index of genera 12. The catalogue itself occupies 582 broad pages, and the distribution and synonymy appear to be very fully given. To criticise such a work in detail would only be possible for a specialist in Diptera, and in any case would occupy much more space than we could give to it; and we have, therefore, confined ourselves to observations on its scope and contents.

Elementary Experimental Science. An Introduction to the Study of Scientific Method. By W. Mayhowe Heller, B.Sc., and Edwin G. Ingold. Pp. 220. (London: Blackie and Son, Ltd., 1905.) Price 2*s.* 6*d.* net.

THE course of work in elementary science presented by the authors of this little book is modelled upon the plan which, it is satisfactory to know, is adopted in all good modern secondary schools. The consequence is that there is little which is new in the volume, though the methods of presenting familiar experiments and of setting forth practical instructions for laboratory exercises supply abundant evidence of the experience and teaching ability of the authors.

The book is quite suitable for the use of young pupils except for the paragraphs containing hints to teachers which are scattered up and down the chapters. It is unwise to lead children to suppose their teachers to be in need of instruction, and it may be asked, "May it not be supposed that most teachers have acquainted themselves nowadays with the aims and methods of elementary science instruction?" In any case, the teacher should not be addressed directly in the book intended for the use of his pupils.

The book is interesting since it shows that in the opinion of some at least of the most enthusiastic advocates of "heuristic" methods of instruction there is a good purpose served by a well-arranged text-book in introducing children to the study of scientific method. Teachers looking for a book containing a sensible, practical course of work in science should examine this one with care.

Astronomischer Jahresbericht. By Walter F. Wislicenus. Vol. vi., containing the literature of the year 1904. Pp. xxxvii+612. (Berlin: Georg Reimer, 1905.) Price 19 marks.

THIS is the sixth year of the issue of this very valuable publication, and it possesses all the vitality of the former volumes. It was thought by the reviewer of the previous year-books that the publication of the branch E, astronomy, an annual issue of the International Catalogue of Scientific Literature, would take the place of the present compilation, since they both for the most part cover the same ground. This, however, seems not to be the case, and perhaps the reason lies in the fact that the volume before us gives in many cases a brief *résumé* of the contents of the book or publication to which reference is made.

The present volume contains 2280 references, and as these with their brief summary of contents cover 595 pages, and an excellent "name" index which follows is responsible for another 17 pages, the matter contained therein is considerable.

The high standard maintained throughout reflects the greatest credit on the compiler and his seven co-workers, and renders the volume a necessary and valuable addition to every astronomical library and observatory.

W. J. S. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Problem of the Random Walk.

THIS problem, proposed by Prof. Karl Pearson in the current number of NATURE, is the same as that of the composition of n iso-periodic vibrations of unit amplitude and of phases distributed at random, considered in *Phil. Mag.*, x., p. 73, 1880; xlvii., p. 246, 1899; ("Scientific Papers," i., p. 491, iv., p. 370). If n be very great, the probability sought is

$$\frac{2}{n}e^{-r^2/n}rdr.$$

Probably methods similar to those employed in the papers referred to would avail for the development of an approximate expression applicable when n is only moderately great. RAYLEIGH.

Terling Place, July 29.

The Causation of Variations.

IT is sometimes said that natural selection has ceased as regards civilised man; but very clearly this is an error. All civilised and most savage races are very stringently selected by various forms of zymotic disease. Thus in England practically everyone is brought into contact with the organisms which give rise to tuberculosis, measles, and whooping-cough; those individuals who are the most resistant to the organisms repel infection (*i.e.* do not fall ill), the less resistant suffer illness but survive, the least resistant perish. Abroad, malaria, dysentery, and many other complaints play a similar *rôle*. Probably no one is absolutely immune to any disease; but since illness only follows invasion of the tissues by a sufficient number of the microbes (the sufficiency of the number varying with the individual attacked), and since the microbes are more abundant in some localities than in others, the stringency of selection as regards any disease is greater in some places than elsewhere. For example, selection by tuberculosis is more stringent in the slums of cities than in the country. It should be noted, also, that resisting power against any one disease does not imply resisting power against any other; thus an individual innately strong against measles is not necessarily strong against tuberculosis. The result of all this elimination by diseases demonstrates the action of natural selection very beautifully. Every race is resistant to every disease strictly in proportion to its past experience of it. Thus Englishmen who have suffered much from tuberculosis are more resistant to it than West African Negroes who have suffered less, and much more resistant than Polynesians who have had no previous experience of it; that is, as a rule, Englishmen, under given conditions, contract the disease less readily, or if infected recover more frequently, or if they perish do so after a more prolonged resistance than Negroes and Polynesians. Negroes, on the other hand, as South American plantation experience proves, are more resistant to malaria than Asiatic coolies, who in turn are more resistant than Englishmen and Polynesians.

Against some diseases (*e.g.* tuberculosis) no immunity can be acquired, that is, experience of the disease confers no increase of resisting power, the disease pursuing a course of indefinite length. Against other diseases (*e.g.* measles) immunity may be acquired, that is, experience of the disease, if not fatal, confers after a definite time a more or less permanent immunity on the sufferer. In the former case the survivors are mainly those who have an inborn power of *resisting* infection; in the latter they are those who have an inborn power of *recovering* from infection. Evolution has proceeded on these lines. Thus Englishmen are less readily infected with tuberculosis than Polynesians, but nearly all Englishmen, like Polynesians, readily take measles, though a much greater proportion of them survive and acquire immunity. Lastly, in relation to such very "mild" diseases as chicken-pox, which render the individual very ill while they last, but cause hardly any elimination, no race appears to have undergone any change; for instance, no race, apparently, is more resistant to chicken-pox than any other race.

The pathogenetic organisms of all prevalent human diseases are more or less entirely parasitic on man. Most of them, therefore, flourish best in crowded populations, where they can pass readily from one susceptible individual to another. Thus tuberculosis is most prevalent in the slums of great cities. An important exception is malaria, the parasites of which require special conditions, and which, therefore, is more prevalent in the open country than in towns. The inhabitants of the eastern hemisphere have been afflicted by a multitude of zymotic diseases for thousands of years. Of old, with the increase of population, the conditions slowly became worse, the stringency of selection became greater, and the human races underwent continual evolution. But before the voyage of Columbus zymotic disease, with the exception of malaria, appears to have been almost, if not quite, unknown in the New World. We have fairly definite accounts of the first introduction of most Old World diseases to this and that aboriginal race, and of the frightful destruction of life that followed, the principal agent of elimination being tuberculosis. With their diseases the European immigrants introduced modern civilised conditions of life, especially churches, schools, and other enclosed spaces in which the natives, crowded together, conveyed infection to one another, and clothes, which acted as a deterrent to cleanliness, and which, besides, harboured the microbes of disease better than the naked skin. As a consequence, except when protected by malaria in extensive forests or when dwelling remote in unsettled regions, the natives rapidly perished. It is a significant fact that, whereas in Asia and Africa every town inhabited by Europeans has its native quarter, no European town in the temperate parts of the western hemisphere (*i.e.* where tuberculosis is most rife) has its native quarter. Published health statistics demonstrate quite definitely that the abnormally high mortality of the natives is caused by introduced diseases. Since civilisation implies a dense and settled population, it follows that no race can now achieve civilisation that has not undergone evolution against tuberculosis and kindred diseases. The case of the Negroes is interesting. In Africa they had undergone some evolution against tuberculosis. In America, when they were first taken to it, the disease prevailed to a comparatively slight extent, especially amongst the agricultural population; but the conditions slowly became worse, and the descendants of the early slaves underwent concurrent evolution. To-day they are able to persist in the northern cities, though their death-rate there is still abnormally high. But though a constant stream of Negro slaves and soldiers (*e.g.* in Ceylon) was poured for centuries into parts of Europe and Africa, they have left no trace on the population. All perished in a few generations, the elimination being so stringent as to cause extinction, not evolution. It is tolerably certain that a fresh immigration of African Negroes to America would end as disastrously.

These facts appear to establish conclusively two truths, first that evolution is due solely to natural selection, and second that variations, except, perhaps, in rare instances, are not due to the direct action of the environment on the germ-plasm, but are "spontaneous." The Lamarckian doctrine is quite out of court. If ever acquirements are transmitted, it should be in the case of the profound and lasting changes affecting the whole body which result from disease; but in no instance is the effect produced by any disease on the race similar to that produced by it on the individual. Thus tuberculosis injures the individual but confers resisting power on the race; measles confers immunity on the individual, but none on the race. Were the Lamarckian doctrine true, man could not persist on the earth. Presumably this is true of all other species, since probably all organisms are subjected to causes of slow deterioration similar to disease. If ever external agencies acting directly on the germ-plasm alter its composition and so cause variations (of any sort) in offspring,

it should be when germ-cells are literally soaked for prolonged periods in some virulent toxin such as that of malaria. Presumably the effect should be a harmful one, and it should act in much the same way on the germ-cells of one individual as on those of another; the race should, therefore, by the accumulation of injury, steadily deteriorate until it becomes extinct; but in no case is this observable. A disease may exterminate a susceptible race, but there is no evidence that it is ever a cause of racial degeneration. The same is true of races exposed to the complex of harmful agencies which surround urban life—filth, over-crowding, lack of light and air, of suitable food and exercise, and so forth. None of the races which have been longest and most exposed to them have become degenerate—for example, the Chinese, the Hindoos, the Egyptians, and the inhabitants of Europe. These races have merely become permanently resistant, preeminently capable of an urban existence. Red Indians and Polynesians perish *en masse* under such conditions. There is not an iota of evidence which demonstrates that the children of peasants if removed at birth to the city would on the average be better developed than the descendants of a line of slum dwellers. The legend that urban families tend to become extinct within four generations is founded on the fact that migration and inter-marriage betwixt town and country is so great that no families purely urban for four generations exist.

Bearing in mind the fact that races grow resistant to all diseases to which they are exposed, the only conceivable non-miraculous cause of evolution (*i.e.* adaptation) is natural selection. But natural selection cannot act when any agency (*e.g.* malaria) causes a drift in a particular direction, *i.e.* when all variations are unfavourable, and offspring tend always to fall below the parental mean. Students of evolution have generally thought of elimination in terms of sudden death as by the agency of carnivorous animals, when the individual who perishes dies in the fulness of his strength, and the individual who survives is strengthened rather than weakened by his efforts to evade destruction. It is clear, however, when considering causes of slow deterioration, which affect practically the whole population during youth, that the doctrine of natural selection is incompatible with the doctrine that variations are caused by the direct action of the environment. It is clear also that natural selection itself must always tend to establish a high degree of insusceptibility to direct action. A greater or lesser degree of susceptibility of the germ-plasm is itself a variation. The more susceptible type of germ-plasm tends continually to be eliminated, and a high degree of insusceptibility established. This is not the same thing as saying that the germ-cells are inviolable and cannot be injured It is only implied that their "hereditary tendencies" are implanted in them almost as firmly as life. The behaviour of somatic cells confirms this view. A gland, for example, may be diseased for twenty years, yet on recovery we do not find a new type of cells; on the contrary, the descendant cells are quite of the old type.

No doubt many instances of the alleged direct action of the environment on the germ-plasm have been recorded. Thus medical men have published statistics to prove that the children of alcoholics and consumptives tend to be insane; but as a rule this evidence is inconclusive in that it fails to demonstrate that the proportion of insane is higher among them than among the offspring of normal parents. Numerous other factors of error, also, are not taken into account. In some cases published by biologists acquirements do not seem to have been clearly differentiated from variations. Thus in the well known case of Weismann's butterflies ("Germ-Plasm," p. 399) we are not told that the darkening of colour produced by a higher temperature was accentuated during subsequent generations by similar treatment, nor that the darkened individuals reproduced their like in the absence of the high temperature. *A priori* there is no apparent reason why acquirements should not be made in the germ-cell stage of the individual as well as during subsequent stages of development. In other cases, as when plants have been removed to a new environment, the effects of a different survival of the fit have not apparently been taken into account. It must be remembered that natural selection not only adapts organisms to changing environments, but keeps them stable in stable environments, and so eliminates the variations which appear in the new surroundings.

It is not necessary, of course, to believe that variations are never caused by the direct action of the environment. Presumably the insusceptibility of the germ-plasm is due to evolution, and evolution is never perfect. It is only necessary to believe that in circumstances normal to the species the insusceptibility is so high that the amount of variations produced by the direct action of the environment is so minute as to be negligible, *i.e.* not a cause of racial change. It is possible that when species are removed to very new environments (*e.g.* European dogs to India or horses to the Falkland Islands) the germ-plasm is sometimes changed by conditions to which natural selection has not rendered it highly insusceptible; but the deterioration which is said to result in such cases is clear evidence of the necessity of this insusceptibility. If it be not established the species must perish.

G. Archdall Reid.

The Empire and University Life.

In your issue of July 6 your powerful advocacy of a higher and broader education in our great universities casts me back in memory to more than fifty years ago, when I first was transported with delight at F. von Schlegel's great generalisation of the unity of the Indo-European family of languages. I was then astounded that Oxford and Cambridge, through so many centuries, had not seen this great truth.

The theological and catastrophetic method had darkened the mental vision of both Oxford and Cambridge; even the mighty Whewell, in 1846, wrote from Cambridge:—"Not only, then, is the doctrine of the transmutation of species in itself disproved by the best physiological reasonings, but the additional assumptions which are requisite to enable its advocates to apply it to the explanation of the Geological and other phenomena of the earth, are altogether gratuitous and fantastical."[1]

From Oxford, her powerful son, the G.O.M., could not rise to feel that the first chapter of Genesis was a sublime poem; he could not rise to feel the truth of the most elementary facts of geology; so enchained was his mind that he could not feel the poetry and spirituality of the "Sacred Books of the East"; the Hindu philosophers and poets give their ideal demi-gods a vast age, even to 900,000 years; but they know that it is poetry and ideal. But Oxford's greatest son could not rise to such elementary generalisation; he saw the great doctrine of "continuity" no wider than the concrete mythology of the Hebrews—he believed in the literal and personal Methuselah of 969 years!

These modern examples of bad method are but glaring "instances" of the general bad method which permeates society, permeates the professions, above all, the professions of theology and medicine.

The Method (see Coleridge) of Oxford and Cambridge in its influence on its sons always reminds me of the words of Sismondi[2]; writing of the "erudition" of the Greeks of the tenth century, Sismondi says:—"Few (of their) books seem better constructed to show the vanity of erudition, and to place in strong contrast a vast extent of knowledge, with a total incapacity of deriving any useful results from it." "Were it necessary to choose between the whole experience which has been acquired and collected from the beginning of time, the whole rich store of human wisdom, and the mere unschooled activity of the human mind, the latter ought, without hesitation, to be preferred. This is the precious and living germ which we ought to watch over, to foster, to guard from every blight. This alone, if it remain uninjured, will repair all losses; while, on the contrary, mere literary wealth will not preserve one faculty, nor sustain one virtue."

We do not want revolution, but an active evolution, both at Oxford and Cambridge, based, as Coleridge said, on the "historic sense."

May I add my personal experience, that I have been able to converse in a more genial, enlightened spirit and

1 "History of the Inductive Sciences," 3rd ed., 1857, vol. iii. p. 481.
2 "Fall of the Roman Empire," vol. ii., pp. 258, 261 (1834).

method with Hindu Brahmans and gentlemen, and with cultured Moslems, in India, than I find it possible to do with clerics, the professional classes, and society magnates in Britain.

It is to be hoped that "more light" will evolve at Oxford and Cambridge, and a higher and truer method permeate their sons.

GUNGA-GUNGA.

A Solar Outburst (?).

REFERRING to the note on solar activity in your issue of July 20, I shall be glad to know whether any correspondent observed a luminous outburst in the tail end of the great spot on the evening of July 16. I had been observing in the afternoon with an 8½-inch reflector, but remarked nothing of the sort. At 5.30, however (the sun having got beyond range of my reflector), I was observing him with a small refractor, power 12, and sun-cap, when I at once noted the luminous appearance in question. It was roundish and about the size of the small spot near following limb, and it was brighter than the bright bridge in the large group. I watched this bright spot until 7.30; next morning it had practically disappeared. Father Cortie courteously informs me that the Stonyhurst magnets were perfectly quiet on July 16, but that next morning, at 8.15, there was a "very small but sudden and sharp movement on both the declination and horizontal force curves." By that time the locality where the luminous appearance occurred would not be far from central meridian. I also noticed a rosy hue pass over the bright bridge of great spot, but this may have been a mistake. I am, however, certain of the luminosity.

Cardiff, July 24.

ARTHUR MEE.

A CENTURY'S PROGRESS IN WARSHIP DESIGN.

THE interesting paper read by the Director of Naval Construction at the summer meeting of the Institution of Naval Architects brings vividly home to us the progress made in the design of warships since Nelson fought, off Cape Trafalgar, our last great sea fight. In our account of the proceedings at the meeting, printed last week, we referred to Sir Philip Watts's paper, but it is worthy of more attention than brief mention in a report of a society's meeting.

We reproduce from among the illustrations accompanying the paper the sheer draught of Nelson's last ship, the *Victory* (Fig. 1). The original drawing of this most famous of all vessels of the Royal Navy was shown at the meeting when the paper was read. We also reproduce the sheer draught of the 36-gun frigate *Syrius* (Fig. 2), as affording an interesting comparison with a modern cruiser. As is well known, the *Victory* was forty years old at the date of Trafalgar, so that as she now floats in Portsmouth Harbour she numbers 140 years. She was, however, reconstructed in 1798, seven years before Trafalgar, and again in 1820. The effect of her first reconstruction is shown by the dotted lines of the engraving. The long time that the *Victory* remained on the active list is indicative of the slower progress of invention that characterised former times. If we go somewhat further back we have a still more striking example in the *Royal William*, a model of which 100-gun line-of-battle ship was shown at the Naval Exhibition of 1891. She was built at Chatham Yard in 1670, was rebuilt at Chatham in 1692 on the same lines as those on which she was originally designed by Phineas Pett, and was again rebuilt at Portsmouth in 1719. As she was not broken up until August, 1813, she was in existence when the battle of Trafalgar was fought; but as Sir Philip Watts does not include her in his table of ships of the Royal Navy, October, 1805, we may conclude that before that date she had ceased to be considered efficient.

The long life of the warships of past times was not due to their more durable construction as compared to modern vessels, but to the lack of that inventive enterprise now made possible, primarily, by James Watt's labours. A steel vessel well built and properly kept up would be practically indestructible with fair treatment; but the same cannot be said of wooden ships. It is not because sound wood in itself is less strong than iron or steel, weight for weight, so much as that it cannot be procured in sufficiently long and conveniently sized pieces, a large number of joints and overlappings thus being necessary; but the chief drawback to wood is that it is not so suitable a material for making joints; as Sir Philip Watts says, "The fastenings cannot develop the strength of the main body of the material." A seam of rivetting in a properly designed steel vessel will join plates to frames or beams, or plates to plates in a way that no buffeting of the winds and waves will affect. That is not the case with the fastenings of wooden ships; as a matter of fact, most of the old men-of-war became "hogged" after some years of service. The frequent reconstruction of wooden vessels of which we read was the result of these conditions.

The causes which thus led to the decay of wooden ships, as individual structures, contributed to the permanence of their respective types, especially in regard to ships of the line. As Sir Philip Watts points out, it was "owing to the limitations imposed on shipbuilding, when wood was the only available material, that length could not be largely increased without reducing to a dangerous extent the longitudinal strength of ships, and the only practicable means of largely increasing the number of guns was to increase the number of decks for carrying them." There were, however, limitations to the extension of vertical dimensions as well as to the increase of horizontal dimensions. A few four-deck ships were built, but the advantages of the extra gun positions thus secured were more than counterbalanced by the defects of a high, unwieldy structure above water. Even three-deckers were at a disadvantage owing to their high sides; they were "worse sailors and less handy in manœuvring than two-deckers"; and, indeed, when one looks at the old *Victory* towering above water, riding to her moorings in Portsmouth Harbour, one wonders how these ships were ever sailed in any direction excepting broad off the wind. The high positions of the guns also necessitated a greater amount of ballast to give stability. All these circumstances joined in confining the naval architect to short ships; and once Phineas Pett had developed construction to the full extent allowed by the limitations of wood as a material, and wind as a source of motion, there was little more to be said. Charnock, speaking of the *Prince Royal*, designed by Pett at the beginning of the seventeenth century, has said, "This vessel may be considered the parent of the identical class of shipping which, excepting the removal of such defects or trivial absurdities as long use and experience has pointed out, continues in practice even to the present moment." That sentence bridges over a period of more than 200 years of the history of naval design.

When it was recognised that iron could be used for the construction of ships—that it was not, as some averred at the time, "contrary to the laws of Nature"—then the horizon of the naval architect widened as when fog lifts at sea. To design a ship of adequate strength became a science, for the stresses that hull structure of given scantling would stand could be calculated with precision; mathematics and a knowledge of physics took the place of bolts and

trenails. Before this era English models had fallen sadly behind those of our chief rivals. It was by hard fighting, not by superiority or even equality of design, that victories were gained for our arms. Creuze, in his "Treatise of Naval Architecture," published in 1846, speaks of the inferiority of British ship design, quoting Charnock to the same effect. "When an English fleet was in chase of a French fleet it was ships which were British built that fell into our possession; but almost on every occasion the French ships could evade ours. The losses sustained in the French Navy by foundering at sea, or by wrecks were principally those ships which had been taken from us. On the contrary, the favourite ships in our fleets were those which had been taken from the French, and the instances in which French ships in our service were ever recovered possession of by them were extremely rare; we as far exceeding them in all that related to the manœuvres and management of ships as they did us in designing them." As is well known, the *Foudroyant*, a two-deck ship captured from the French in 1758, served as a model for a new class, or, again to quote Creuze, "a very superior class of man-of-war which was adopted."

It was not, however, with the abandonment of wood that England ceased to follow the lead of France in ship construction. We remember that the first iron-clad ocean-going war vessel, *La Gloire*, was French; and Sir William White in 1887 said, "it must be frankly admitted that the lead taken by the French on both the steam and ironclad reconstructions was the primary cause of most subsequent activity in warship building."

We dwell on this point because it illustrates the evil of neglecting the application of scientific principles to practical affairs. Happily, since the period to which we have referred Great Britain has done much to remove the reproach under which she formerly rested. The labours of Scott-Russell, Rankine, William Froude, and many others raised ship design in this country to a position of which we may well be proud. Some of the later workers, like the late William John, have passed away, but, happily, the majority—and we may cite the author of the paper as among the most distinguished—are still with us. It is fair to add that it is to the establishment of the Institution of Naval Architects this improvement is mainly due; and, since its foundation in 1860, the application of scientific principles to ship design has made progress rapid beyond all precedent. Annual meetings bring together the leading members of the profession for the interchange of ideas, and in the *Transactions* of the institution may be found memoirs by the best authorities on all subjects connected with the science of naval architecture.

It is well to remember, however, that, whilst there is much room for congratulation, the need for effort towards progress still exists, and perhaps to a greater degree than ever. For long after the introduction of steam propulsion, Great Britain, as the leading shipbuilding nation, held a position not seriously challenged. We gave examples to the rest of the world; others took their practice from us. Of late, however, our supremacy has been attacked. There are shipyards and marine engine works, many of them splendidly equipped, in all the most important countries, and we may depend every effort will be made to employ them fully and develop them further. The naval Powers are determined to construct their navies within their own domains, and some foreign Governments are giving inducements to shipowners and shipbuilders of a substantial nature, and such as are not offered in this country. It is well to remember that Germany for some time past has not only possessed, but has constructed within her own domains, the mercantile vessels which hold the premier position in the world.

In shipbuilding, as in nearly all other manufacturing industries, we must neglect no chances. To design a complex structure such as a high-class modern steamship needs an amount of accurate knowledge intelligently applied—that is to say, an amount of science—which is only within the com-

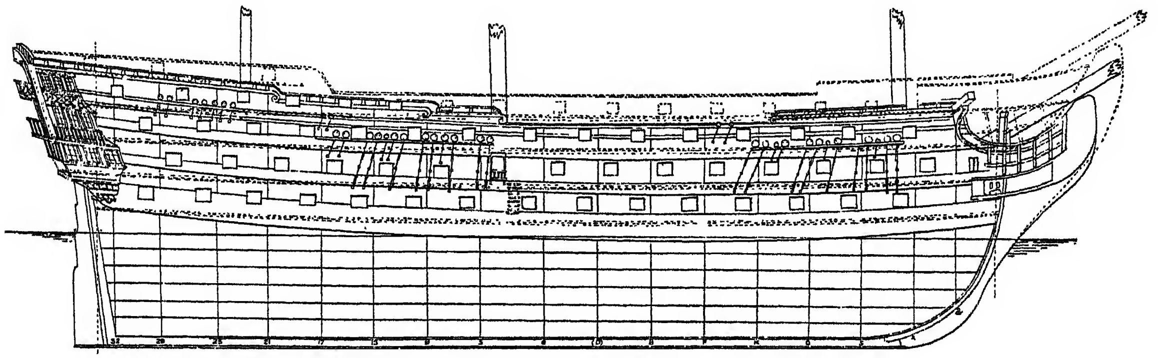

FIG. 1.—Navy Office, June 6, 1759. Sheer draught of 100-gun vessel *Victory*. Length on the gun decks, 186 ft.; Length of the keel for tonnage, 151 ft. 3[illegible] in.; breadth extreme, 51 ft. 10 in.; breadth moulded, 50 ft. 6 in.; depth in hold, 21 ft. 6 in.; burthen in tons, No. 2162[illegible]; the dotted outline shows the vessel as altered.

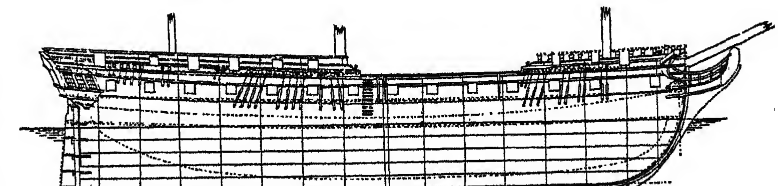

FIG. 2.—Navy Office, September 30, 1795. Sheer draught of 36-gun frigate *Syrius*. Length on the lower deck, 148 ft. 10 in.; length of the keel for tonnage, 124 ft. 0[illegible] in.; breadth extreme, 39 ft. 7 in.; breadth moulded, 38 ft. 11 in.; depth in hold, 13 ft. 3 in.; burthen in tons, No. 1033[illegible].

mand of those having every advantage for its acquirement. We here say "design," not copy, for the man or the nation that copies must necessarily lag behind those who originate. It is not a good sign—it is distinctly a bad sign—that, in spite of the efforts of some public-spirited and thoughtful members of the Institution of Naval Architects, shipowners and shipbuilders at large have not subscribed the really modest sum needed for establishing the proposed experimental tank at the National Physical Laboratory. It is by the aid of such a tank that the data needed for the scientific design of a vessel can be worked out in their completeness; and such accurate knowledge as we have about resistance of ships is due to researches made by the aid of models in tanks. It is many years since an Englishman, Froude, established the first tank at Torquay, and, by his incomparable experimental work and scientific deductions, put at our disposal the information needed to prosecute further inquiries in this direction; and now, after more than thirty years, although we claim to be the leading shipbuilding nation of the world—as we are in regard to bulk of tonnage constructed—Mr. Yarrow has to depend on a German tank when he seeks information as to the resistance of vessels in varying depths of water. If our shipowners would devote a small part of the energy they expend, and an infinitely small part of the money they waste on freight-wars to an attempt to improve the designs of their vessels, it might tend to the stability of the British shipbuilding industry and to more satisfactory balance-sheets; it certainly would to a more worthy record of the country's progress in ship design.

Sir Philip Watts, who, as Director of Naval Construction, has at his command the well equipped and admirably staffed Government tank at Haslar, does not feel the need of such an establishment, and naturally does not refer to it in his paper. He gives, however, a sketch of the plan followed in scarphing frames and planking together so as to reduce the working of the different pieces on each other. The science of the metallurgist has removed that necessity by giving us a material which enables the side of a ship to be made practically a continuous structure. The outer planking of ships of the line at the time of Trafalgar was 8 inches to 4½ inches thick above water, and planking on the inside of the frames was from 4 inches to 5 inches thick. The frames themselves composed almost a solid wall, so that a combined thickness of nearly 2 feet—the thickness of the iron armour on the *Inflexible*—was available for resisting shot. Great attention was paid to seasoning timber; but when it came to a case of metal construction our ancestors were often a little at fault. "The older ships of the Trafalgar period were iron fastened and sheathed with copper. Considerable trouble was, however, experienced by the corrosion of the iron fastenings, so much so that in some cases, after three or four years, the ship was rendered unfit for foreign service. The intervention of substances such as felt, tarred paper, &c., between the copper and the wood bottom failed to protect the iron entirely, and at one time the Board of Admiralty contemplated discontinuing the sheathing of ships lying in ordinary and fitting it to them immediately before going to sea." Thus do we see how the want of a little knowledge of natural laws caused inefficiency and loss of money; but there was excuse for our predecessors which we, who have their accumulated experience, cannot plead.

Sir Philip Watts gives some interesting figures as to the cost of the older ships, and these may be compared with that of modern vessels. In 1719 the cost of the *Royal William*, of 1918 tons, was 30,800*l*., or about 16*l*. per ton. Whether or not this refers to Pett's *Royal William*, reconstructed in 1719, is not certain, but probably it does. In that case a good deal of the original structure might have remained, thus lessening the cost. The *Royal George*, of 2046 tons, built in 1756, cost 54,700*l*., or 26·7*l*. per ton. "In 1800 ships of the line cost 21*l*. per ton, whilst in 1805 the cost had risen to 35·4*l*. per ton." These figures presumably refer to displacement tonnage, but whether guns are included we are not aware; we will conclude they are not, and see how former figures compare with those of the present day. The first class battleship *King Edward VII.*, of 16,350 tons displacement, is to cost 1,410,901*l*., excluding guns and ordnance stores; whilst the guns will come to 89,070*l*., bringing the total cost to within a few pounds of a million and a half. This would be somewhat over 86·2*l*. per ton, without guns, as compared to 35·4*l*. per ton at the date of Trafalgar. If, however, we could measure cost in terms of fighting efficiency we should doubtless find that we now get more for our money than our fathers did in 1805, for the *King Edward VII.* could have engaged the whole of the British Fleet at Trafalgar with the allied fleet thrown in. In armament the advance has been no less striking. The old cast-iron smooth bores, with their wooden truck carriages, were trained by handspikes, used as levers under the brackets, and by side tackles; and they were elevated by handspikes, being held in position by quoins. Sir Philip Watts says that "a 32- or 24-pounder, fought on the lower deck, had a range of only about 2000 to 2500 yards with 8° elevation, and of about 1500 yards with 4° elevation. The powder charge was generally one-third to one-quarter the weight of the shot. At close quarters a 24-pounder was said to be able to penetrate nearly 5 feet of solid oak and an 18-pounder half this amount." These were not the heaviest guns in the service at the beginning of the last century, there being 42-pounders also; but guns of this nature, designed to form the principal armament for the lower decks of the largest battleships, were found to be too heavy to be worked quickly by the rude appliances then in use. A still heavier piece was later introduced, namely, the 95cwt. 68-pounder.

We have not information as to the thickness of solid oak which the round shot fired from these heavier natures would penetrate, but we may compare the 5 feet that would be pierced by the 24-pounder with the power of the guns of the present day. The modern 12-inch wire-gun of the Royal Navy, weighing 50 tons (about twenty times as much as the 32-pounder), is estimated to penetrate 42 inches of wrought-iron at muzzle velocity of 2580 foot-seconds and a muzzle energy of 30,280 foot-tons; at 1000 yards the penetration would be 38 inches of wrought-iron, at 2000 yards 34·6 inches, and at 3000 yards 32 inches. The penetration of Krupp steel armour at 3000 yards would be but 14 inches. These results are with uncapped projectiles. The longer 12-inch guns of Armstrongs or of Vickers will penetrate more than 51 inches of wrought-iron and will fire two rounds per minute.

It will be seen from the above facts how enormously the powers of both attack and defence have increased during the century. They would seem to have progressed in about equal ratio, for Sir Philip Watts says that "the capability of the wooden ship to take punishment from the guns of her time was, except in one important respect, much the same as that of a modern ironclad." The important respect, of course, refers to the shooting away of spars and rigging.

A table given by Sir Philip Watts comparing the weights apportioned to the different elements of design in a battleship of 1805 and of a modern battleship respectively is interesting. The old ship is one of 74 guns, and 20 per cent. of the total displacement was awarded to general equipment as against 4 per cent. for the 1905 battleship. Armament in 1805 was 10 per cent. of the displacement; in the present day it is 19 per cent. The propelling arrangements are somewhat in the nature of a surprise, masts, sails, and rigging absorbing 8.5 per cent., and steam machinery only 10.5 per cent. of the displacement. There is, however, to be added to the latter figure 5.5 per cent. for coal, but this is more than balanced by the 6.5 per cent. of the weight apportioned to ballast for giving the stability needed under sail. Armour is naturally the great point of difference, for it takes up 26 per cent. of the displacement of a modern battleship. As against this but 35 per cent. of the total displacement is needed for the construction of steel hulls, whilst the wooden hull absorbed 55 per cent. of the total tonnage. It must be remembered, however, that the construction of the "wooden walls" was far more massive than was needed for ordinary purposes, and a good part of the 55 per cent. might be set down as wooden armour. The remarkable thing is that iron plates were not applied earlier, before the French constructors set us the example; or, rather, it would be remarkable were the very conservative nature of the old admirals not remembered.

THE LIGHT-PERCEIVING ORGANS OF PLANTS.[1]

THE subject of this most suggestive book has already been dealt with by the author in a preliminary way.[2] In its present form it has gained greatly in force and interest, and whether or no we are finally converted to Prof. Haberlandt's views there can be no doubt that they are worthy of serious attention.

It is well known that the majority of leaves have the power of placing themselves at right angles to the direction of incident light, but the question of how the light stimulates the leaf to perform the curvatures and torsions which bring it into the "light position" is a problem which hitherto has hardly been attacked.

The first question to be solved is what part of the leaf is sensitive to light. By covering the blade of the leaf with black paper, &c., Haberlandt shows that the principal and most delicate sensitiveness resides in the blade, although a coarser and secondary sensitiveness to the incident light is found in the stalk. It results from this part of the inquiry that the lamina of the leaf must contain the organs for light-perception, if such organs exist. Anything corresponding to a visual organ may be expected to be on the surface, although in such a translucent organ as a leaf this does not necessarily follow. It may, however, be said that Haberlandt is amply justified in looking for what he calls the ocelli of plants in the epidermis covering the upper surface of the leaf. We may therefore narrow the problem thus. Imagine a horizontal leaf illuminated by light striking it obliquely from above at 45°; such a leaf is not in the "light position," and will execute a curvature through 45°, in fact until it receives light at right angles to its surface. Then curvature ceases and the leaf remains in a state of equilibrium—satisfied, as it were, with the "light position." The question is how the leaf differentiates between oblique and perpendicular illumination. Direct observation suggests an answer. If the epidermis of such a leaf as that of *Begonia discolor* be removed by a surface section, and mounted upside down and illuminated from below, then with a low power of the microscope it can plainly be seen that there is a bright spot of light on the basal (inner) walls of the epidermic cells. It can further be seen that the relation of the spot of light to the surrounding zone (which is more or less dark) changes when the specimen is obliquely illuminated. Thus in the case of the obliquely illuminated leaf we should have to imagine that the leaf is stimulated to curvature by the fact that the spots of light are not central in the cells, and that curvature ceases when the brightest illumination is once more central. Thus the plasmic membrane of the basal wall of each epidermic cell is supposed to have a quasi-retinal function by which the leaf is believed to orientate itself in regard to light. There is here, as Haberlandt points out, a certain resemblance to the mechanism by which plants are by many botanists believed to react to gravitation, namely, by the pressure of solid bodies on different parts of the cell walls, just as the statoliths (otoliths) of certain animals, by pressure on different parts of the membrane of the statocyst, enable them to orientate themselves in space.

Haberlandt shows that the epidermic cell is well fitted to concentrate light. It is very commonly lens-like in form, its outer wall being convex, its inner wall either plane or curved. Haberlandt shows by geometrical construction that, taking the refractive index of the cell sap as equal to that of water, the focus is usually at a point either within the cell or below it in the other tissues. In either case a central illuminated region and a surrounding dark zone is produced on the basal cell wall. A further development of this type is the papillose epidermic cells which give the velvety appearance to certain tropical leaves. This does not differ essentially from the first described type, but it has, according to the author, certain advantages which will be referred to later on. It must not be supposed that all leaves have lens-shaped epidermic cells; some leaves, known as aphotometric, are indifferent to the direction of incident light, and even in photometric leaves Haberlandt shows that discrimination is possible without the epidermis playing the part of a lens. Where the outer wall of the epidermis is flat, it often occurs that the inner wall bulges into the subjacent tissues or projects into them in the form of a truncated pyramid. In this case, when the light strikes the leaf at right angles, the central part of the basal wall, being more or less parallel to the surface, is more strongly illuminated than its peripheral parts, which are oblique. Thus without any lens-effect we get stronger illumination in the central region of the basal walls of the epidermis; and this may conceivably serve as a means of orientation.

The most conclusive proof of the author's theory is given by the results of placing the experimental plants under water. If he is right in claiming a lens-function for the epidermic cells, it is clear that immersion in a fluid which has approximately the same refractive index as the cell sap must interfere with the plant's power of light-perception; and this is, in fact, the outcome of his experiments.

His first experiments (p. 89) were made with the hop (Humulus). Here, as in other cases, the stimulus of light is perceived by the leaf, and less perfectly by

[1] "Die Lichtsinnesorgane der Laubblätter." By Dr. G. Haberlandt o. ö. Professor der Botanik a. d. Universität Graz. Pp. viii+143 (Leipzig: Engelmann, 1905.) Price 6s. net.

[2] *Berichte d. deutsch. bot. Gesellschaft*, Bd. xxii., 1904 (February), and in an address given in 1904 before the Gesellschaft deutscher Naturforscher und Aezte, and published by Barth, of Leipzig.

the leaf-stalk. Four leaves were immersed, two (D) having their leaf-stalks darkened with tin-foil, while the stalks of the other two (L) were exposed to oblique light. After three or four days the D leaves showed no signs of taking up the light-position, while the two L leaves showed well marked curvature towards that position. The experiment is of importance, since it shows that immersion in water does not prevent heliotropic curvature by interfering with respiration or by depressing the energy of the plant in any other way. The only explanation seems to be that of the author, viz. that in the leaves (D) with darkened stalks the lens-like epidermic cells of the leaf-blade are the only organs of light-perception, and they being thrown out of action by the presence of water, perception (and therefore curvature) is absent.

Experiments of the same type were made with a like result on *Ostrya vulgaris* and *Begonia discolor*. It is to be regretted that the light-perceiving organs of such leaf stalks as were sensitive to light under water were not investigated.

A striking result was obtained with Tropæolum (p. 92). The leaves of this plant are unwettable, and when immersed remain coated with a silvery mantle of air. The waxy layer, which gives this quality, may be removed by painting the surface with dilute alcohol without injury to the leaves. The result of immersion is that the normal leaves protected by a layer of air react normally to oblique illumination, whereas the wettable leaves have lost the power of so reacting. This interesting result suggests to the author a new function for the waxy "bloom" of leaves, *i.e.* that it saves them from being blinded by a shower of rain. This theory he extends to velvety leaves, the strongly papillated epidermic cells of which stand up like islands when the surface of the leaf is wetted (p. 65). This is a striking fact in relation to the distribution of velvet-leaved plants, which are especially common in damp tropical regions.

Another section of Haberlandt's evidence depends on the existence of highly specialised lenses. One of the most curious is that of *Fittonia Verschaffeltii* (Acanthaceæ), shown in Fig. 1. Here we have a

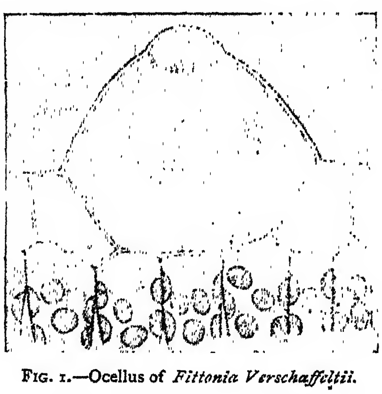

FIG. 1.—Ocellus of *Fittonia Verschaffeltii*.

dwarfed, two-celled trichome, of which the apical cell has the form of a biconvex lens. In this case there is a division of labour, the light focused by the lens-cell being perceived by the large basal cell. Direct experiment shows that, as might be expected, painting the leaf with water in no way interferes with the effect, since the lens is raised above the layer of wet. Similar ocelli occur in *Impatiens mariannae*, and here, as in Fittonia, it is interesting to note that the ordinary epidermic cells, among which the ocelli occur, are markedly bad lenses.

Quite a different type of lens occurs in *Campanula persicifolia*; here (Fig. 2) the formation of a spot of light does not depend on the form of the epidermic cell as a whole, but on the existence of a lens-shaped silicified region in the outer wall of the cell. These structures only occur in perfection in a shade-loving form of the species, where they were noted by Heinricher, who was unable to suggest a function for them. Direct observation proves that they are highly effective lenses. Similar organs are found in *Petraea volubilis*. We must pass over a number of other interesting specialised organs, but it is of importance to note that whenever ocelli occur they

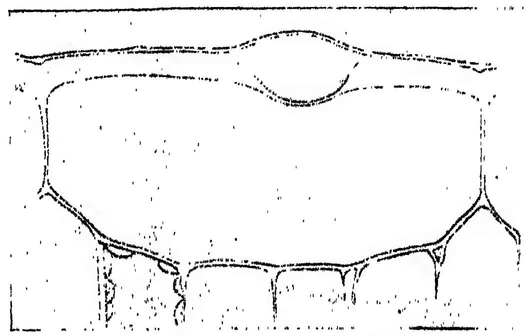

FIG. 2.—Ocellus of *Campanula persicifolia*.

are to be found on the upper, and not on the lower, surfaces of leaves. It is also particularly interesting to find that ocelli tend to occur especially near the edges of leaves, *i.e.* just in those regions where the amount of movement, corresponding to curvature through a given angle, is greatest.

The author has once more earned the gratitude of his fellows by his suggestive discoveries and speculations He must be allowed to have made out a strong case for his theory, but he would be among the first to grant that more work is needed before it can be considered as completely established.

F. D.

RECENT PUBLICATIONS IN AGRICULTURAL SCIENCE.

EVERY civilised State has recognised a special duty towards its farmers in the way of endeavouring to secure them against the purchase of adulterated manures, fraudulent feeding stuffs, and dead or impure seed, but different countries have taken very various means towards securing the desired end. The United Kingdom, probably because its representative farmers are men of substance, rather holds by the old *caveat emptor* maxim, and is content with providing the farmer with a machinery for getting an analysis below cost price, but a machinery sufficiently cumbrous to ensure that no one sets it in motion. Other nations, less intent, perhaps, upon a plausible case in Parliament, and more concerned in getting the thing itself done, have devised various systems of controlling the trade in such materials, so as to ensure that the smallest farmers shall be supplied with seed or manures reaching a certain standard of purity. The laws and methods adopted for securing such a control in the various States Prof. Giglioli passes in review,[1] giving an account of the testing stations, the regulations, the fees, and even notes on the working details employed in the labor-

[1] "Concimi, Mangimi, Sementi, &c., Commercio, frodi, e repressione delle frodi, Specialmente in Italia." By Italo Giglioli. Pp. xvi+759. (Rome: Annali d'Agricoltura, 1905.)

atories. To anyone interested either in the technique or in attempting to secure a more thoroughgoing system in this country, Prof. Giglioli's book will provide a storehouse of information.

We have before had occasion to comment upon the gigantic undertaking of the United States Department of Agriculture, which has embarked on the preparation of a map of the soils of the whole country on a scale of one inch to the mile, accompanied by analyses of each soil type with descriptions of its agricultural features and suitability to particular crops and methods of management. Criticism has not been wanting of the manner in which the work is being executed, but when something like 26,000 square miles are being surveyed and mapped in the course of a year at a cost of about 12*s.* per square mile little more than a first approximation can be expected. Objection has been taken to the system of adopting a local name, *e.g.* Norfolk sand, attaching it to a given soil type, and using it all over the continent for soils of that category, whatever their situation or origin. But the argument is after all a formal one, and the value or otherwise of the survey can only be judged by the farmer on the spot, who finds that it does or does not represent his own soil conditions and assist him to utilise them to the best advantage.

To the foreign reader these volumes[1] are chiefly valuable as giving details of the nature of the soil, the climate, and other factors of the notable farming areas in the United States. Here one can compare the conditions under which the very different wheats of the north-west or of the Pacific slope are grown, or make out the climatic and soil requirements of such crops as cotton in Louisiana or tobacco in Connecticut. We miss in the present volume the photographs of the country which, to the outsider at least, were one of the most interesting features in the former issues.

For many years Mr. T. Jamieson has been carrying on a series of agricultural experiments, or rather demonstrations, on a comparatively small scale, but in a very careful and neat fashion. Reports on the work done have been issued from time to time, and now the results, which extend over something like twenty-eight years, have been gathered together in the little volume before us.[2] The experiments illustrate the well known principles of plant nutrition, and the account of them affords a brightly written *résumé* of the elementary facts connected with manures and their application to various crops. When here and there we read that this or that fundamental fact has been discovered or proved by the Aberdeenshire Research Association, much as though Mr. Jamieson should tell us that he has discovered water is composed of eight parts of oxygen and one of hydrogen, we can only admire the innocence in which Mr. Jamieson has managed to preserve his mind. Not for him the knowledge of good or evil that comes of reading other men's work, either past or contemporary. We miss, indeed, in this volume some of Mr. Jamieson's engaging speculations, as when, in his 1903 report, he told us that potash "appears to be the element chosen in nature to neutralise acidity, and facilitate transmission within the plant, for which purpose it is specially fitted by its alkalinity, solubility and soft or slippery character. Soda, which closely resembles it, but is of a harder drier nature (as seen in the soft Potash Soap as compared with the hard Soda Soap) is unable to take the place of Potash in plants, as has been found by former experiments." But as a result the book forms a sufficiently sound and quite clearly written introduction to agricultural chemistry, which, like a visit to Mr. Jamieson's orderly demonstration plots at Glasterberry, may well be useful to set farmers thinking about the way their crops grow.

NOTES.

THE address on "Imperial Defence" delivered by Lord Roberts at a special meeting of the London Chamber of Commerce on Tuesday was a clear statement of the unsatisfactory condition of the armed forces of this country, in comparison with those of other great military Powers. Lord Roberts believes that we could not hope to be successful against an enemy of anything like equal strength, trained and organised as are the armies of leading nations. It appears, therefore, that we are as unprepared for war as Sir Norman Lockyer showed we are for the industrial competition of the future, in his presidential address to the British Association; and as to the way to remedy our deficiencies Lord Roberts's address—*mutatis mutandis*—supports the views expressed on that occasion. Higher education and scientific study must be applied to the arts of war as well as to those of peace if our country is to occupy a position in the first rank of progressive nations. Less attention must be paid to such trivial matters as the shapes of headdresses or the cuts of jackets, and more must be given to education and scientific training from early youth. In the war in the Far East, the Japanese have been successful because of their superior intelligence and scientific spirit. Let our statesmen learn from this that intellectual efficiency is now a truer safeguard of a nation than physical strength.

THE Government Eclipse Expedition organised by the Solar Physics Observatory will leave for Gibraltar on Friday. The expedition, in charge of Sir Norman Lockyer, K.C.B., will tranship there to H.M.S. *Venus*, which will proceed to Palma, where, by permission of the Spanish Government, the instruments will be erected. Mr. Howard Payn, one of the volunteer observers, is already there superintending the location of piers for the instruments. It was originally intended to observe at Philippeville, as Bona is occupied by two American parties, but the French Government would not give the necessary authorisation.

THE official party of the British Association, consisting of the president-elect and general and sectional officers, as well as other leading representatives of science, left Southampton on Saturday last by the mail steamer *Saxon* to attend the meeting of the association in South Africa.

DR. A. C. HOUSTON has been appointed director of water examinations under the Metropolitan Water Board.

THE death is announced, at the age of forty-six years, of Mr. H. Lamb, of Maidstone, author of "The Flora of Maidstone."

A REUTER telegram from Halifax, Nova Scotia, states that the Arctic exploration steamer, the *Roosevelt*, sailed from Sydney, Nova Scotia, on July 26. Commander Peary said he hopes to succeed in reaching the Pole, if not early in 1906, then the next year. He proposes to start on his final dash for the Pole from the eighty-fourth parallel.

ACCORDING to the *British Medical Journal*, a new society has been started in Paris for the scientific study of tuber-

culosis. The work of the society is to be purely scientific. The membership is restricted to thirty members, who are to be chosen irrespective of school or opinion, and there is to be no president. The members are in turn to preside at the meetings.

At the opening meeting of the council of the Liverpool Institute of Tropical Research, held on Monday, Sir Alfred Jones, the chairman, remarked that in many respects countries such as Germany, France, and Belgium are applying scientific methods to their commercial enterprises, especially to those conducted in the tropics, with greater success than Great Britain; and that it is necessary for the British merchant to bestir himself and take advantage of every assistance that science can offer. He guaranteed the institute 1000*l.* a year for four years; and among other guarantees were:—Mr. W. H. Lever, 1000*l.* a year for four years; Mr. T. Sutton Timmis, 250*l.* a year. It is proposed to take steps to obtain a charter of incorporation for the institute.

The tenth session of the International Statistical Institute was opened on Monday by the Prince of Wales, as honorary president of the institute, and of the Royal Statistical Society. In the course of his address, the Prince said:—"My revered grandfather, the late Prince Consort, who did so much for the progress of science, was instrumental in rendering special assistance to the first effort of statistical science to secure for itself an assured and prominent position in the ranks of the older and better recognised sciences. Quetelet, whose name stands preeminent in that science, was at one time the Prince Consort's mathematical teacher, and later on his close personal friend. It was on the occasion of our great exhibition of 1851 that a large and distinguished company of statisticians was assembled in London. It was chiefly at the instigation of Quetelet that the question of instituting periodical international congresses for the discussion of questions of common interest and international concern was proposed. In consequence of this proposal an international organisation was formed, and the first international statistical congress was held in Brussels in 1853. Later on, in 1860, London welcomed the international congress, which met under the presidency of the Prince Consort, who, in his opening address, remarked:—'The importance of these international congresses cannot be overrated. They not only awaken public attention to the value of these pursuits by bringing together men of all countries who devote their lives to this work, and who are thus enabled to exchange their thoughts and varied experiences. They also pave the way to an agreement among different Governments and nations to follow up these common inquiries in a common spirit, by a common method and for a common end.' This watchword of the congress of 1860 I would endeavour to commend to the congress of 1905 as worthily embodying its aims and its objects. National and social tendencies are to-day capable of increasingly accurate measurement with the aid of the very numerous statistical tabulations which now exist. In the future all branches of social science must look for their advancement and increase of precision to the continually improving character of the raw material furnished them by statisticians. For scientific progress, however, a primary essential is active and effective cooperation among scientific workers in all countries in order that publicity can be given to their results and uniformity obtained in the collection and arrangement of data for the purpose of their common employment."

The first number of a periodical for the publication of original investigations in economic biology will appear on September 29. The new magazine will be entitled the *Journal of Economic Biology*, and will be edited by Mr. W. E. Collinge, with the cooperation of Prof. A. H. R. Buller, Prof. G. H. Carpenter, Mr. R. Newstead, and Mr. A. E. Shipley, F.R.S.

Nos. 1 and 2 of vol. xxvi. of Notes from the Leyden Museum are entirely occupied by a memoir by Dr. O. Finsch on the birds collected by Dr. A. W. Nieuwenhuis in Dutch Borneo, more especially in the districts of Mahakam and Kajan. No less than 209 species were represented in the collection. The paper is illustrated with a coloured plate of the new species *Poliolophus nieuwenhuisi*, as well as with a map of the districts traversed by the explorer.

The most generally interesting item in the June number of the *Victorian Naturalist* is the description by Mr. J. A. Hill of fights between two species of ants. One of the two is the large soldier-ant (*Formica purpurea*), a species which forms huge nests, and is capable of overpowering such creatures as small snakes. Nevertheless, this species is vanquished and exterminated by a small black ant scarcely one-third its size, the battles between the two often lasting months, and the victors finally taking possession of the nests of the vanquished.

At the annual meeting held in May last of the Boston Society of Natural History, the curator of the museum reported (*Proceedings*, vol. xxxii., No. 5) that the plan for re-arranging the collections referred to at the previous meeting had been in great measure carried out, and that the New England mammals and birds now occupy all the cases on the main floor of the building with the exception of one temporarily devoted to the palæontology of the district. This special attention to the proper display of the local fauna is a feature which should be copied by all provincial museums.

The July number of the *Zoologist* contains a full report of a lecture on the migration of birds delivered at the recent International Ornithological Congress by Mr. Otto Herman, director of the Hungarian Central Office of Ornithology. The lecturer directed special attention to work which had been accomplished in Hungary in the matter of recording the dates of arrival and departure of migratory species by means of the services of a very large number of observers scattered all over the country. It has been ascertained, for example, that it takes one hundred and five days for swallows to complete their migration throughout Europe, that is to say, from Gibraltar in the south to Lulea in the north, the young being fully fledged in the former locality by the time the old birds have reached the latter. Even in Hungary itself the period of arrival may last as long as seventy days, the time that the species spends in that country averaging one hundred and sixty-seven days.

In recording a collection of fishes obtained by Dr. B. Dean from Negros Island, Philippines, Messrs. Jordan and Seale (*Proc. U.S. Nat. Mus.*, No. 1407) take occasion to mention that a large percentage of the small species, so often neglected by collectors, appear to be new. Taken generally, the Philippine fish fauna seems to be very similar to that of the Indo-Malayan archipelago, although a few species are identical with Indian forms. In the course of their list the authors give an example of one of those transpositions of generic names which are so hostile to the real progress of zoology. In this particular

instance the name Amia, so universally in use for the American bow-fin, is employed to designate the perch-like fishes commonly known as Apogon.

WE have recently received five parts of the *Proceedings of the U.S. National Museum*. In the first of these (No. 1408) Mr. T. Gill contributes the results of investigations into the life-history of the sea-horses (Hippocampus), a subject which has hitherto received but little attention. One of the illustrations shows a male discharging the young from its brood-pouch. In the second (No. 1409) Mr. B. A. Bean describes and figures an adult specimen of the extraordinary Japanese goblin-shark (*Mitsukurina owstoni*). The third (No. 1411) contains a list, by Mr. H. C. Oberholser, of birds collected by the well known traveller Dr. W. L. Abbott in the Kilimanjaro district, several of which are described as new. A descriptive list of a collection of caterpillars and chrysalises of Japanese Lepidoptera, by Mr. H. G. Dyar, constitutes the fourth fasciculus (No. 1412); while in the fifth (No. 1413) Mr. W. H. Asmead records Hymenoptera new to the Philippine fauna, with descriptions of new species.

PROF. A. GIARD, of the Sorbonne, has favoured us with separate copies of three articles by himself from vol. xxxix. of the *Bulletin scientifique de la France et de la Belgique*. In the first of these, entitled "Pœcilogonie," the author discusses whether in the case of organisms of which the adults are more or less similar to one another, while their embryogeny is different, more importance should be attached to the evolutionary dissimilarities or to the similarity of the adults. The title for the phenomenon is new. The second paper will delight the hearts of lovers of the oyster, the author remarking at the conclusion of this communication, which is entitled "La Prétendue Nocivité des Huîtres," that he "could wish there existed in the world no other cases of typhoid save those induced by eating tainted oysters." In the third communication Prof. Giard discusses the drift (*tendance*) of modern morphology and its relations to other sciences.

A PAPER on the development of the ascus and on spore formation in the Ascomycetes, by Mr. J. H. Faull, published as vol. xxxii., No. 4, of the *Proceedings of the Boston Society of Natural History*, gives a detailed description of the nuclear changes for *Neotiella albocincta*, *Sordaria fimicola*, and a species of Hydnobolites. The origin of the asci was in most cases traced to the penultimate or terminal cells of ascogenous hyphæ, and it was found that the uninucleate stage of the young ascus was always preceded by a fusion of two nuclei. From his observations of the method by which the spores are delimited, the author favours the view that the ascus is homologous with a zoosporangium, and would derive the Ascomycetes from such a group as the Peronosporeæ or Saprolegnieæ.

IN a paper forming No. 1405 of the *Proceedings of the U.S. National Museum*, Mr. R. MacFarlane, the chief-factor of the Hudson Bay Company, contributes a series of highly interesting notes on mammals collected and observed in the northern Mackenzie River district, North-Western Territories of Canada. For two-and-forty years (1852–1894) Mr. MacFarlane was stationed as a post and district manager in these territories, and therefore had unrivalled opportunities for observing the fauna in its days of abundance. Unfortunately, as he himself confesses, except when stationed at Fort Anderson the author did not take full advantage of these opportunities either in the matter of collecting or observing; nevertheless, such observations as have been recorded are of the highest interest and value, and one cannot help regretting that they were not published in a British or colonial serial, and also that the author's services were not long ago enlisted on behalf of the British Museum. The paper was, indeed, it appears, prepared to a great extent for publication at Cumberland House, the headquarters of Cumberland District, in the winter of 1890–1, but for various reasons it was not completed, and several sheets of the MS., together with various memoranda, were subsequently lost. The paper is a perfect mine of information with regard to the fur exports of the Hudson Bay Company in the old days.

TWO memoirs have lately been published by the Carnegie Institution of Washington which contain results of interest in reference to problems of heredity. The first of these, by W. E. Castle, discusses the phenomena of coat characters in guinea-pigs and rabbits. Three alternative pairs of coat characters in guinea-pigs are shown to conform generally to Mendel's law. These are:—albinism *v.* pigmentation, smooth *v.* rough coat, and long *v.* short coat, the first named in each pair of characters being recessive with respect to the second. The author distinguishes between characters which are recessive and those which are latent; by the latter he means certain "dominant" features which depart from Mendel's law in being capable of renewed activity under certain conditions even in "recessive" gametes. The facts given in the paper supply abundant illustrations of the variety of conditions under which blended inheritance, as in Mendel's Hieracium experiments, may occur in place of the strict Mendelian segregation. In the second paper, which is by D. T. Macdougal, assisted by A. M. Vail, G. H. Shull, and J. K. Small, a full account is given of the various forms of Œnothera which have constituted the chief material for De Vries's "mutation" theory, and of the relation between them. It is shown that *O. lamarckiana* is in all probability a true and independent species native to America; and the authors record the re-discovery of the habitat of *O. grandiflora*, the place of habitat of which in the American flora had become doubtful. Both memoirs are well illustrated by woodcuts and half-tone plates.

DR. H. MIGLIORATO announces in vol. ii., part ii., of *Annali di Botanica* that he is preparing an analytical dictionary of vegetable teratology as a subsidiary work to Penzig's "Pflanzen Teratologie," and requests that workers in this subject will cooperate by sending copies of their papers to him at 89b rue Panisperna, Rome.

PROF. F. W. OLIVER, in an article in the *Biologisches Centralblatt* (June 12) on the newly discovered seeds of the Carboniferous ferns, summarises the results of recent investigations in fossil botany which have led to the formation of a separate group, the Pteridospermeæ, including the Lyginodendreæ and Medullosæ. The paper is illustrated with figures of sections and a model of the seed in its cupule of *Lagenostoma Lomaxi*.

WE have received from Brazil the first number of the *Revista da Sociedade Scientifica de São Paulo*. It contains the first instalment of a report, written in French, of a voyage made in 1825 by Hercules Florence from the Tiete to the Amazon by the Brazilian provinces of St. Paul, Matto Grosso, and Gran Para. There is also a valuable memoir on the Brazilian Tabanidæ, written in German, by Dr. A. Lutz, director of the bacteriological institute of the State of São Paulo. Lastly there is a paper, written in Portuguese, by Erasmo Braga, on the gold mines of Ophir.

THE seeding of pastures is a matter of primary importance to owners of grazing land, and it is certain that many farmers will obtain useful information from the experiments conducted under the direction of Mr. A. N. M'Alpine, which are described in Bulletin No. 31 of the West of Scotland Agricultural College. Fourteen different mixtures were tried, three containing rye-grass in excess, three without rye-grass, and four were special mixtures; of the latter Timothy and cock's-foot mixtures in suitable quantity were especially efficacious in checking Yorkshire fog and bent grass. With respect to rye-grass, it was demonstrated that both the perennial and the Italian varieties should be sparingly sown.

THE cultivation of oranges in Dominica is discussed by Mr. H. Hesketh Bell in No. 37 of the pamphlet series issued by the Imperial Department of Agriculture for the West Indies. Mr. Hesketh Bell has been growing oranges for some years on two experimental stations, and has shipped sample boxes at different times to England which have realised remunerative prices at Covent Garden. Experience has proved that budded oranges are much superior to seedlings, and the varieties "Parson Brown" and "Jaffa" are recommended as being hardy and prolific, while the "Washington Navel" also appears to thrive well. Emphasis is laid on the necessity for exercising the greatest care in handling and packing the fruit, so that Dominica brands may secure a good name on the market.

THE banana industry was unknown to Costa Rica twenty-five years ago, says a writer in the *Journal of the Society of Arts* (July 28), but it has reached such proportions, especially within the last few years, that bananas now form the main export of the country. At the close of 1904, about 50,000 acres were devoted to banana growing in Costa Rica. The trade was exclusively confined to the United States until 1902, when the fruit was exported to England, with gratifying results. France, Germany, Italy, Spain, and other European countries do not as yet consume the banana, but as soon as a substantial increase in the acreage is reached, and with the present facilities for transportation and the use of ships equipped with cold storage, the market will be extended probably to those countries. The amount exported from Port Limon during the five years ended with June 30, 1904, was as follows, in bunches:—1900, 2,804,103; 1901, 3,192,104; 1902, 4,427,024; 1903, 5,261,600; and 1904, 5,760,000. The following figures show the probable cost and profit on a tract of 100 acres planted in bananas. Original outlay:—land (4*l.* per acre), 400*l.*; reducing land and bringing it to a banana-bearing condition (10*l.* per acre), 1000*l.*; total, 1400*l.* Gross returns, 180 stems per acre per annum, 1116*l.* Expenses:—cutting and hauling the fruit, and keeping the plantation clean, 288*l.*, manager (20*l.* per month), 240*l.*; total, 528*l.* Net return on investment, 588*l.* Under favourable conditions, a banana plant may give a stem of fruit in nine months, but it generally takes from fifteen to eighteen months for the average plantation to be in full bearing. The life of a plantation varies according to the fertility of its soil and topographical situation. Some soils may need a rest in six or seven years, while others may last practically for ever, as in cases where periodically enriched by alluvial deposits. It is understood that fine flour can be made from bananas, and that fibres from the leaves and stalks could be extracted and successfully worked, but as yet nothing in this direction has been done in Costa Rica.

THE *Engineering and Mining Journal* directs attention to the increasing tendency to use copper as the collecting agent instead of lead in smelting gold and silver ores. Smelting on the copper basis is decidedly cheaper than on the lead basis.

WE have received part i. of the annual report of the director of the Philippine Weather Bureau for the year 1903, containing hourly observations of atmospheric phenomena at the Manila Central Observatory. The assistant director contributes a useful climatological summary for the year, together with monthly and daily amounts of excessive rainfall that have occurred since 1865. Photographic illustrations are given of the havoc wrought by one of the two destructive cyclones which traversed the archipelago. Unfortunately, there was no good anemometer at any of the towns that suffered most severely. Manila itself escaped these violent storms.

THE Hamburg Meteorological Institute has issued vol. xiii. of "Deutsche überseeische meteorologische Beobachtungen," 1905. As may be inferred from the title, the work contains observations made at places abroad, under German control. In the present case it refers entirely to some twenty-two stations in German East Africa, and the tables have been prepared and printed with the liberal assistance of the Colonial Department of the German Foreign Office. It contains more than 300 pages of valuable observations, and is a very important contribution to the climatology of Africa, with explanatory details relating to each of the stations. For some of them hourly observations are given from self-recording instruments; at others eye observations have been made several times daily.

A PAPER entitled "Records of Differences of Temperature between McGill College Observatory and the Top of Mount Royal, Montreal," by Prof. C. McLeod, was read at the meeting of the Royal Society on June 8. The chief object of the paper was to show the advantage of Prof. Callendar's electrical recorders, in connection with the use of platinum thermometers, in obtaining trustworthy indications of the variations of temperature at a distance in a situation inaccessible for the greater part of the winter. The horizontal distance between the stations was 3300 feet, and the difference of altitude 620 feet. The first year's working (July, 1903, to May, 1904) showed that range of variation was considerable, and often changed very rapidly; on some occasions the temperature at the higher station was 6° F. or 7° F. above the lower, on others it was 25° below. A comparison of the records showed that any marked change of temperature at the lower station was almost invariably preceded by a similar change at the higher station at an interval of twelve to twenty-four hours. It is claimed, we think with fairness, that this system of recording meteorological data appears to overcome the difficulty and expense of maintaining a staff of observers at an inaccessible station.

AT the last annual meeting of the Royal Meteorological Society, the president, Captain D. Wilson Barker, gave an interesting address, illustrated by a number of lantern slides, on the connection of meteorology with other sciences. He pointed out several of the most evident influences of meteorology to the geological observer, such as rain, ice, snow, &c., and the rock-splitting action of great changes of temperature. As regards zoology, the influence of meteorology on animal life is all-pervading. Among the most common results are mentioned the winter sleep of various animals, and the summer sleep of some fishes and

reptiles. Dr. Dickson, Dr. Mill and others are studying the effects of changes of climate on sea organisms generally. Agriculturists are more dependent on the weather than any other class of persons. Were it possible to issue forecasts for a longer period in advance, farmers would be much benefited. Captain Barker considers that the effect of weather upon health has not received a fair amount of scientific notice. While medical officers write voluminous reports on the public health, many of them ignore the meteorological conditions of the districts under review. We think we are justified in claiming exception for the reports of the various registrars-general, which contain carefully prepared meteorological statistics.

IN the *Rendiconti* of the Lombardy Academy, xxxviii., 2, Prof. Ernesto Pascal gives a classification of the various forms of twisted sextic formed by the intersection of a quadric and a cubic, with special reference to the number of their real tritangent planes.

WE have received the third edition of Dr. Richard Dedekind's pamphlet on "Stetigkeit und irrationale Zahlen," which may now fairly claim a place among the mathematical classics. It originated about the year 1858, when the author was charged with a course of lectures on the calculus, and found no satisfactory treatment of the continuity hypothesis in existence. On November 24, 1858, Dedekind discovered a definition of continuity which he imparted to Durège a few days later, and the present pamphlet was written in 1872 in commemoration of his father's jubilee.

IN the Bulletin of the American Mathematical Society for June, Dr. Edward Kasner directs attention to a significant dialogue in Galileo's "Discorsi e dimostrazioni mathemetiche" of 1638, in which modern concepts of infinity as laid down by Bolzano, Cantor, and Dedekind appear to have been foreseen by that philosopher. In this dialogue Salviati points out to Simplicio that since every number has a square there must be as many squares as there are numbers, but, on the other hand, since there are many numbers which are not squares there must be more numbers than squares. In answer to Simplicio's question "What is to be our conclusion?" Salviati gives the following remarkable reply:—"I see no escape except to say: the totality of numbers is infinite, the totality of squares is infinite, the totality of roots is infinite; the multitude of squares is not less than the multitude of numbers, neither is the one greater than the other; and, finally, the attributes of equal, greater and less are not applicable to infinite but solely to finite quantities."

MR. J. J. HICKS, of Hatton Garden, has submitted a two-foot rule designed by Mr. Scott which is worthy of notice. When opened out like an ordinary carpenter's rule one face shows inches and sixteenths along one edge and millimetres along the other, while between them the divisions are repeated in juxtaposition for the purpose of more accurate comparison. It is the other face of the rule, however, where the greater novelty is to be found. Here there are four double comparison scales of English and French measures of length, weight, capacity, and fluid measure. Taking the first as an example of the system, a length of about 10 inches shows comparison quantities from 1 inch to 60 miles juxtaposed, but the divisions are not equispaced, as in that case nothing much less than a mile would be visible. They are therefore spaced logarithmically, so that the first inch covers a space of nearly half an inch. This is divided into eighths, and each of these by estimation could be read to tenths. The next two inches occupy the same space, and so, of course, do the next four, and so on. In a distance of $1\frac{1}{2}$ inch or 38 millimetres, a reading is increased ten-fold. Of course such comparison scales have the advantage of the ordinary slide rule that at all parts of the scale readings are made with the same proportional accuracy. For instance, on the scale now referred to 1 inch is opposite 25 and a small half-millimetre, $11\frac{1}{2}$ yards is opposite $10\frac{1}{2}$ metres, 5 miles is half the thickness of the line beyond 8 kilometres, and similarly 50 beyond 80. In short, the accuracy with which any of these comparison scales may be read is the same as that which would apply to a slide rule in which the A line from 1 . . . 100 was 3 inches long. For quick and fairly accurate comparison of lengths, weights, cubic and fluid measures, this face of the rule is most convenient.

WE have received several papers dealing with projects (not performances) of artificial flight the general character of which is sufficiently shown by the following brief summaries:—Arnold Samuelson, in a lecture published at Hamburg (London: E. and F. N. Spon), asserts that all flying animals (insects and birds) have flat, not curved, wing surfaces, that the normal air-pressure on a thin supporting plane is independent of the angle of incidence at which the plane moves forward, that the pressure on a rectangular plane decreases uniformly from front to back, giving a centre of pressure at one-third the distance from the front to the back surface, and other conclusions equally at variance with many generally accepted theories. Dr. Federico Sacco, in a paper entitled "L'Aerovoie" (Turin: P. Gerboni), proposes a captive balloon attached to a small trolley running along a kind of elevated cable railway as a cheap and rapid means of locomotion which would be unaffected by such trifling terrestrial obstacles as rivers, mountains and lakes; in windy weather a voyage on such an apparatus would doubtless be highly thrilling. For the argument of cheapness Dr. Sacco is responsible. M. René de Saussure, writing in the *Revue scientifique* for May 27, describes the "hélicoptère aéroplane" of MM. H. and A. Dufaux, which, roughly speaking, consists of a pair of double-surface gliders placed fore and aft, with two screw propellers arranged side by side between them rather nearer to the front than to the back gliders. Of this apparatus only small models have been tried, and a large sized machine 8 metres long and 3 metres broad which has been constructed has not yet been experimented on; the authors, however, give full details as to how to start the machine and to land safely. The latter operation, as shown in the diagram accompanying the article, bears a rather ominous resemblance to the motion of a dynamically unstable glider previous to capsising. We cannot close the list without referring to a paper by Mr. F. W. H. Hutchinson, read at Cambridge and published in *Knowledge and Scientific News* for June, describing experiments on models with bird-like wings, which have already yielded some interesting results in the study of natural flight. The wings in this case were not assumed to be flat, but of the curved form, which the author describes as the "Hargreave curve."

MESSRS. WITHERBY AND CO. have issued the prospectus of a book on "The Birds of Hampshire and the Isle of Wight" which they have in preparation. The work is by the Rev. J. E. Kelsall and P. W. Munn, and is claimed to be the first complete history of the birds of Hampshire and the Isle of Wight published. The work will contain a large-scale coloured map, and be illustrated by reproductions of drawings and photographs.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF JUPITER'S GREAT RED SPOT.—In No. 4034 of the *Astronomische Nachrichten* Mr. Stanley Williams gives the results of the observations of the Great Red Spot on Jupiter made by him during the period June 20, 1904–January 21, 1905.

During this opposition the phenomena proved of exceptional interest on account of the vagaries in the relative motions of the Red Spot and its immediately surrounding features.

When the first observation was made, on June 20, it was seen that the immense mass of dark material, known as the south tropical disturbance, had, after making a complete circuit of the planet, again overtaken and enveloped the Red Spot. On July 26 nearly all this dark material had drifted past the Red Spot, which in August was quite separate, but very faint.

Mr. Williams's observations also afforded further evidence of the variable rate of motion of the Great Red Spot.

SUN-SPOT SPECTRA.—During the year ended March, 1905, Mr. W. M. Mitchell, of the Princeton Observatory (N.J.), made an exhaustive series of observations of that part of the sun-spot spectrum which is included between F and α. These observations took note of the two separate features of the spot spectrum:—(1) the nearly continuous absorption known as the spot-band, and (2) the affected Fraunhofer lines. A rapid survey of the whole region was first made on each observing day, and was followed by an exhaustive examination of some smaller portion. In regard to the first of the above features, Mr. Mitchell arrived at the conclusion that the band-lines are lines which do not appear in the Fraunhoferic spectrum at all, and he submits facts in favour of this view.

In observing the affected Fraunhoferic lines, the observer recorded nine different phenomena (*e.g.* widening, reversal, obliteration, &c.), and in his table of the 680 lines which he observed in the spot spectrum, he classifies each line according to the manner in which it was affected. The intensities of the widened lines, their intensities in the normal solar spectrum, the number of times each line was observed, and various other details concerning the affected lines are also recorded in the table.

Each element involved is then considered separately, and a number of valuable conclusions are deduced. Whilst vanadium and titanium are the most important elements concerned in sun-spots, as previously shown by Young, Cortie, and Lockyer, Mr. Mitchell finds that manganese plays an important *rôle*, 45 per cent. of its lines being affected. A striking comparison is drawn between the behaviour of certain manganese lines in the successive observations of the great sun-spot of February last. On February 3 and 4 they were noted as being strongly reversed, whereas on March 3 they were no longer reversed, but were excessively widened and very hazy.

The following general conclusions were arrived at by Mr. Mitchell, and agree, in general, with those recently published by Prof. Fowler in the Monthly Notices:—(1) Lines frequently seen in the chromosphere are, with two exceptions, but little affected in spots; (2) high-level chromospheric lines are not affected in spots; (3) lines greatly affected in spots are seen but rarely in the chromosphere.

From his observations and conclusions Mr. Mitchell deduces that sun-spots are, at least, below the chromosphere, and are probably caused by the heated vapours from the lower levels oozing through and vaporising the clouds of the photosphere (*Astrophysical Journal*, No. 1, vol. xxii.).

AN INTERESTING ASTEROID, OCCLO [475].—Owing to its large southerly declination, $-62°$, at the time of its discovery, the minor planet Occlo was looked upon as of special interest, and when the orbit was computed and found to have a greater eccentricity than that of any other known asteroid the interest in this object was increased. This great eccentricity suggested that Occlo might be looked upon as the connecting link between the asteroids and the periodic comets. In order that the object should not be lost sight of, Prof. Kreutz had an ephemeris for 1905 computed, and this was communicated to Mr. R. H. Frost at Arequipa, who successfully photographed the planet's trail, with the 24-inch Bruce telescope, in April, 1904. The plates have now been measured by Mrs. Fleming, and the positions of both ends of the trail on April 4 and on April 7 determined. The results are given in Circular No. 101 of the Harvard College Observatory.

OBSERVATIONS OF PHŒBE.—Saturn's ninth satellite, Phœbe, was photographed by Mr. R. H. Frost at Arequipa on four nights during May, and the following positions have been obtained from measurements of the plates:—

Date 1905	G.M.T. h. m.	Exp. m.	Dist.	Difference in decl.	Position angle
May 9	21 3	112	10′·6	+5′·8	56°·8
,, 10	20 40	120	11·0	+6·4	54·4
,, 12	20 49	120	11·6	+6·3	57·1
,, 13	20 48	145	12·0	+6·6	56·6

The above quantities all refer to the position of the satellite in regard to Saturn's centre. A comparison of these positions with those computed from Dr. Ross's ephemeris shows that on the mean date, May 11, the computed distances should be diminished by 0′·3, and the position-angles should be increased by 0°·0 (Harvard College Observatory Circular, No. 102).

PERIODS OF THE VARIABLE STARS S SAGITTÆ AND Y OPHIUCHI.—From a discussion of the observations made by himself, combined with those of other observers, M. M. Luizet has deduced the following elements for the light-curve of the variable star S Sagittæ (Ch. 7149):—

$$\left.\begin{array}{l}\text{Maximum } 2409863{\cdot}33 \text{ (M.T. Paris)} \\ \text{Minimum } 2409860{\cdot}37 \quad\quad ,,\end{array}\right\} + 8{\cdot}38209\text{d. (E.} - 389)$$

The light-curve of this star presents a double oscillation, and, according to M. Luizet's scale, the magnitude varies between 5·4 and 6·2.

For Y Ophiuchi (Ch. 6404), the same observer finds that M. Hisgen's elements,

$$\left.\begin{array}{l}\text{Maximum } 2408694{\cdot}25 \text{ (G.M.T.)} \\ \text{Minimum } 2408688{\cdot}03 \quad\quad ,,\end{array}\right\} + 17{\cdot}1207\text{d. E.},$$

as published in No. 3424 of the *Astronomische Nachrichten*, agree very well with his own recent observations. From a comparison of these observations with those made by Mr. Sawyer, it appears that during the last fifteen years the magnitude of Y Ophiuchi has slightly increased, but this apparent increase may be due to the difference of observer and of observing conditions (*Astronomische Nachrichten*, No. 4030).

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE seventy-third annual meeting of the British Medical Association was held at Leicester last week under the presidency of Mr. Cooper Franklin, surgeon to the Leicester Infirmary. The proceedings were conducted in twelve sections, and were well attended, nearly 1000 members registering their names.

Mr. Cooper Franklin chose for his presidential address the subject of medical education, past, present, and future. He dealt with the various Acts of Parliament regulating medical education and practice, the condition of medical education in London forty years ago, and insisted on the necessity of a good general education if the medical student were to become a good practitioner, and advocated a study of Latin and Greek. He said:—"I think the advantages of a good classical education early, to a man entering our profession, cannot be over-rated. Nothing will, or can, make up for it; there would not be so many candidates deficient in ordinary spelling and composition if there had been a good classical education. To my mind there is nothing really superior to the old-fashioned Latin and Greek training, but it seems hopeless to insist nowadays upon the retention of Greek. I think it is twenty-five or thirty years ago since, in the matriculation examination of the University of London, students were allowed to take up German instead of Greek. I venture to think that, so far as medical students are concerned, that was a retrograde step. I do not envy the student sitting down to learn his anatomy who has not learnt even a little Latin

and Greek; his Gray's 'Anatomy,' perchance, in front of him, his Latin dictionary on one side, and his Greek lexicon on the other. The student, too, must not begin to specialise too soon; he wants a liberal education, an education for its own sake. This goes when the technical education begins—that is, when he leaves school or college to learn to be a 'doctor.'"

Dr. Henry Maudsley delivered an address on medicine, present and prospective, in which he discussed preventive medicine, heredity in disease, &c. He sounded a note of warning with regard to our present sanatorium treatment of tuberculosis which may be quoted:—"But is phthisis so very curable in these special hospitals, nowise endued with any special grace, I imagine, by reason of their being called sanatoriums? Adequate statistics are not yet available, but thus far the modest outcome of experience seems to be that many patients who are sent in the early stage of the disease recover, if they are kept long enough; that most of those in a more advanced stage improve while there, frequently relapsing afterwards; and that those who are badly diseased ought not to be sent at all. Is that, after all, to say much more than might be said of sensible treatment before the erection of sanatoriums?

"Can we, again, eliminate the predisposing influence of heredity? Actual tubercle may not be inherited, but the poor constitutional soil inviting and suiting the bacillus still passes from parent to child; and we do not get rid of the essential fact by changing the name. Do we, indeed, in the end get such a valuable addition to the life-capital of the nation? It is easy enough, noting that some 60,000 consumptives die annually in England and Wales—I do not vouch for the figures—fancifully to rate the value of each life at an arbitrary figure and then by multiplication to make an appalling computation of the loss to the community; but is the loss so real? Might not the ultimate cost to the commonwealth be greater were these persons to go on living and breeding in it? An addition to the nation's life-capital is all very well, but the quality of the capital counts for a good deal, and it will not count for much if it is not realisable. What does the realisation amount to in practice? The patient who comes out of the sanatorium recovered or improved must usually go back to his former work and surroundings; he cannot adapt the world to the weakness of his nature and its ideal needs, but, like other mortals, must adapt himself to the rude world and perforce do much as they do. That is what he quite naturally does; returns to his work and his old ways, perhaps gets married if he is not married, and begets children who can hardly have the confidence of a good descent. Meanwhile, when he relapses, he sows bacilli broadcast, thus multiplying such life-capital to fulfil its ordained function in the universe, that apparently being to make away with weak mortality."

The address in surgery by Mr. C. J. Bond, surgeon to the Leicester Infirmary, dealt with ascending currents in mucous canals and gland ducts. The results of a number of experiments proved that by some means or other, and under certain conditions, particles of an insoluble substance, such as indigo, inserted into the orifices of a mucous canal or duct are conveyed along the mucous channel in a reverse direction to that taken by the contents of the tube, or by the secretion or excretion of the glands along such ducts. The conditions which seem to favour this passage are—some interference with the normal flow of the contents of the mucous tube or duct; some arrest or diversion of secretion, such as is produced by a fistulous opening, though it is by no means necessary that this should be complete.

In the section of medicine an interesting discussion on the treatment of sleeplessness was opened by Sir Lauder Brunton. Many of the speakers dwelt on the importance of indigestion and of high arterial tension in inducing sleeplessness, and Dr. Collier (Oxford) considered that much of the present day insomnia might be referred to over-education, especially in preparing for scholarships, the successful competitors often suffering after the age of nineteen years from nervous failure and insomnia. He thought that the occasional employment of narcotics was of value in breaking a vicious circle before the habit of sleeplessness was established.

In the section of State medicine an important discussion on hospital isolation was introduced by Dr. George Wilson (Warwick), who stated that the deductions he would bring forward were the outcome of thirty-two years' experience. With regard to small-pox isolation, he contended for a special block at the general infectious hospital, and, in his opinion, there was very little risk of the spread of infection. With regard to scarlet fever, he stated that hospital isolation had failed in reducing the incidence and mortality of the disease. He was also sure that it did not cause the presence of the milder form of the infection, and was strongly in favour of separate isolation rather than aggregation in large wards.

Several speakers considered that hospital isolation for scarlet fever was a failure, and a resolution was adopted requesting an inquiry by the Local Government Board into the subject.

In the section of industrial hygiene the subject of physical deterioration naturally attracted a good deal of attention, and an important discussion was introduced by Dr. Dawson Williams (London), who, by means of several tables illustrating a series of observations on the height and weight of boys in primary schools, showed that after the eighth year of age the weight of boys of the artisan classes was very much below the average, this fact being more noticeable in the lowest grade schools. The same remarks applied to the height of boys, though in a less degree. The first striking statement about physical degeneration was made some years ago by Mr. J. Cantlie, who challenged any person to produce a Londoner of the fourth generation. This challenge had never been answered. Dr. Dawson Williams attributed this physical deterioration to various causes, among which he mentioned—improper feeding in infancy; the fact that among the poorer classes mothers worked hard almost up to the time of their confinement; intemperance in fathers, which was said by French authorities to be more injurious to the children than maternal intemperance; and the practice of large numbers of children in London sitting out of doors until midnight, which involved a great expenditure of nervous energy.

Mr. William Hall (Leeds), in a paper on the influence of environment on physical development, said that fifty years ago the slum mother was much more sober, cleanly, and domestic than she was to-day. She was better nourished herself, always suckled her children, and after weaning them gave them nutritious bone-making food, which she prepared at home. This had all been done away with by our elaborate education system, costing 20,000,000*l.* yearly. Children were now fed on cheap stale food, well seasoned with condiments, which educated them for the love of stimulants in later life and produced also a tendency to scurvy, rickets, and purpura. A little while ago he had examined more than 100 adult skeletons in the crypt of Hythe Church, where they had lain for several centuries. He was struck by the fact that the bones were small but not rickety, the bony palates not much vaulted and the alveolar arches regular, and the teeth that remained were good. It had been said truly that there were hundreds and thousands of our countrymen now living whose skeletons, if preserved, would some day show highly vaulted bony palates, contracted alveolar arches, anterior protrusion of the upper jaws, the remains of unsound teeth, and abundant general signs of rickety bony framework. It was remarkable that Jewish children in the slums were superior to Christian children in physical development, which was due to the fact that the pregnant Jewess was better cared for, that 90 per cent. of the infants were fed on breast-milk, and that during later childhood they were abundantly fed on bone-making material. Eggs and oil, fish, fresh vegetables, and fruit entered largely into their diet. Yet the Jews had not been taught to safeguard their pregnant wives and to nourish their growing children by the instructors in the modern and costly State education which they were told at Oxford was to be at the root of everything.

Prof. R. J. Anderson (Queen's College, Galway) remarked that he thought it would be a most important thing to secure a complete anthropometric survey of the whole of the British Isles. He doubted if improper food was the chief cause of physical deterioration, because, in his opinion, food had of late years greatly improved in quality.

Mr. W. D. Spanton (Leeds) considered that the most prominent causes of physical degeneration were—efforts to rear premature and diseased infants, absurd educational high pressure, cigarette smoking in the younger generation, and late hours at night; in fact, the love of pleasure, and ergophobia in all classes of society. He considered that there was too much cheap philanthropy, that life was made too easy for the young poor, and that by modern educational methods proper parental discipline was rendered almost impossible.

Mrs. F. M. Dickinson Berry (London) said that in her opinion children in London schools were not underfed so much as improperly fed, and that they preferred to eat bread and pickles, dried fish, &c., and had to be forced to eat a proper dinner. She quite endorsed Mr. Hall's remarks about Jewish children.

In the section of pathology, a discussion on the relationship of heredity to disease was opened by the president, Dr. Mott (London), in an interesting and suggestive paper. He exhibited charts of hereditary hæmophilia and ataxy with statistics of longevity, presenility, psychoses, and neuroses bearing on these and other diseases.

Mr. Charles Bond contributed a paper on sex-correlation and disease, with special reference to deaf-mutism. While deaf-mutism occurs almost equally in males and females, in any given family the incidence is almost limited to the members of one sex, and when members of both sexes in one family suffered the births were either twin or contiguous.

Mr. C. Hurst described experiments on the correlation of sex. When black and yellow cats were crossed, all male kittens were yellow, all female kittens tortoiseshell, but in the second generation the colours were uniformly distributed between the two sexes.

In the section of tropical diseases, an important paper on human tick fever in the Congo Free State by Dr. Todd and the late Mr. Everett Dutton was read. The conclusions arrived at were:—(1) that tick fever is clinically identical with relapsing fever, and has for a pathogenic agent a spirillum; (2) the spirillum is probably the *Spirochaete Obermeieri*; (3) a tick, the *Ornithodorus monbata*, can transmit the spirillum from animal to animal; (4) the transmission is probably not simply mechanical, but a developmental cycle is passed in the body of the tick.

In the naval and military section, Fleet-Surgeon Beadnell read an interesting paper on some dynamical and hydrodynamical effects of the modern small-bore bullet, in which he claimed that the so-called "explosive" effects of the modern bullet were due to sudden enlargement of the "impact area" resulting from a modification either in the form or in the motion of the projectile. Many of the "explosive" phenomena were due to eccentricities of flight such as the various "spinning-top" and "pirouetting" motions of the bullet.

An invitation to hold the annual meeting of the British Medical Association next year in Toronto was cordially accepted.

SOLAR AND TERRESTRIAL CHANGES.

IN a recent article we referred to the formation of an International Commission to deal with the important question of the possible action of solar changes on the earth's atmosphere. We stated that a meeting is to be held at Innsbruck in September. We are now enabled to give some details of the meeting at Cambridge last year.

The members assembled in the Old Library of Pembroke College on Thursday, August 18, and letters were read from the following:—Prof. H. H. Hildebrandsson, Prof. H. Mohn, General M. Rykatcheff, Prof. G. Hellmann, Dr. A. Paulsen, Hofrath J. M. Pernter, Prof. S. P. Langley, M. A. Angot, Prof. J. Violle, Prof. J. Hann, Mr. A. S. Steen, Prof. W. Köppen, Prof. A. Riccò, Prof. G. E. Hale, Prof. F. H. Bigelow, Mr. W. G. Davis, Prof. K. Ångström, Mr. A. R. Hinks.

The members present proceeded to the election of a president and secretary, and it was unanimously resolved that Sir Norman Lockyer, director of the Solar Physics Observatory, South Kensington, be elected president, and Sir John Eliot, of Bon Porto, Cavalaire, formerly meteorological reporter to the Government of India, secretary.

It was resolved to add the names of MM. Max Wolf, Scheiner, Julius, and Wolfer to the commission if they should be willing to serve.

At the next meeting the name of Sir Arthur Rücker was added to the commission.

The following question was considered:—

"(1) The selection of (*a*) meteorological, and (*b*) magnetic elements, which should be collated for the purpose of comparison with solar observations, and the form in which the observations might be presented with the greatest advantage for the purposes of comparison. The preparation of a list of meteorological and magnetic observatories which should be asked to contribute observations for the purpose."

It was resolved

(1) That, in the first instance, for the purpose of comparison with solar phenomena, the meteorological observations to be considered should be monthly means of pressure, rainfall and temperature (including maximum temperature and minimum temperature).

(2) That the members of the commission be requested to communicate to the secretary a short report on the data available in their respective countries, and the number of years over which they extend.

(3) That the members of the commission be requested to make suggestions with regard to additional stations from which it is desirable that data should be obtained in view of the comparison of solar and terrestrial data.

(4) That the secretary be requested to consult Dr. Chree as to the stations from which magnetic data are at present available, and to refer to a paper by Prof. von Bezold as to additional magnetic stations from which information is desirable, and to circulate the information among the members of the commission, it being understood that the data appropriate for the purposes of comparison are monthly means of the three magnetic elements for the quiet days and data as to magnetic storms.

A letter from Prof. Hale was laid before the commission.

At the third meeting the questions of the selection of meteorological stations and of the establishment of additional meteorological stations were again considered, and it was resolved that the members of the commission should hand in their list of selected stations to the secretary after the close of the British Association meeting, and that it would be desirable that observations should be obtained from two stations in the Pacific. The stations selected were Tahiti and Numea, to be established by the French Meteorological Bureau.

The name of Mr. A. L. Rotch was added to the commission.

The letter received from Prof. Hale suggesting cooperation of the commission with the committee on solar research of the National Academy of Sciences was read. It was resolved that the commission thank Prof. Hale for his letter, and express their desire to cooperate with the committee on solar research of the National Academy of Sciences on questions of common interest.

Mr. Rotch was requested to communicate this resolution personally to Prof. Hale at the conference at St. Louis.

The question of the selection of solar observations for the comparison of data was taken into consideration.

A scheme prepared by Messrs. Riccò and W. J. S. Lockyer was read and provisionally approved.

(1) *Suggested observations of the sun for direction, intensity, and amplitude of "boiling of the limb."*

Present observations:—

Twenty years' observations made in Palermo and Catania, and (?) many years' observations in Madrid.

(2) *Number, area, and position of spots.* Existing arrangements suffice.

(3) *For visual observations of prominences on limb, it is suggested that America or Japan be invited to contribute.* (Places widely separated in longitude required.)

Monthly values of the percentage frequency of prominences for every 5° of latitude north and south.

(4) *Sun-spot spectra.*

Available observations are taken at the Solar Physics Observatory, South Kensington; Poona in India; Stony-

hurst in England; and Kodaikanal in India; and are sufficient for the present.

(5) *Spectroheliograph.*

(1) "Discs" in "K" light { Kensington, Chicago, Kodaikanal, Catania (later).

(2) "Limb" in "K" light ditto.

At the fourth meeting further consideration was given to the question of the solar observations which it is desirable should be collected for the purposes of comparison.

(1) It was resolved, that in connection with the observations of solar radiation, observations of the transparency of the air should be made, more especially

(*a*) on the visibility of distant and high mountains when possible;

(*b*) photometrical observations of Polaris.

(2) It was resolved that a circular be addressed to the various meteorological organisations, asking them to send to the secretary for the purposes of the commission a copy of the publications of their offices embodying the data specified in resolution of August 19, and that the organisations be also requested to obtain and forward copies of similar publications from the colonies and dependencies of their respective countries.

(3) It was resolved that a circular should be sent in the following terms:—The commission desire to direct attention to the concluding paragraphs of Prof. Violle's report to the International Meteorological Committee 1903, and would be greatly obliged if the commission could be informed of the arrangements for observing solar radiation adopted at the observatories of the various meteorological organisations and the methods employed to render the observations comparable with those of other observatories.

(4) Mr. Shaw reported that an apparatus for recording solar radiation was in process of being established, and tested at the Cambridge Observatory, and that Mr. W. E. Wilson, of Daramona, who had presented the apparatus to the observatory, had promised a note upon the apparatus for the information of the commission.

At the fifth meeting the question of the magnetic observations for the purposes of comparison was taken into consideration.

It was resolved in connection therewith:—

That the establishment of magnetical observatories in about lat. 70° N. (*e.g.* Bosskop in Norway) and in very high latitudes of the southern hemisphere is of the highest importance for the advancement of science.

Prof. Riccò informed the commission that it is intended to establish in Italy or Sicily a magnetic observatory with self-recording instruments belonging to the Italian Meteorological Office.

The secretary was directed to ascertain from the members of the commission whether they consider it desirable that a meeting should be held at Innsbruck next year (1905).

It was also resolved that the secretary should report to the International Meteorological Committee the proceedings of the meetings of the commission held here, and ask that the proper steps be taken to bring before the International Association of Academies their suggestions relating to Government action.

Letters from Messrs. Bigelow and Davis were read. It was resolved that Prof. Pernter's letter should be translated and given in the proceedings.

Prof. Riccò informed the meeting that he had been charged by Prof. Rizzo to say that he will willingly undertake to carry out any investigation the commission may be pleased to entrust to him, and it was resolved that Prof. Rizzo should be thanked for his offer, and that a written communication be addressed to him later.

It was agreed that all communications for the commission should be received at a central address, viz. the Solar Physics Observatory, South Kensington.

It was further resolved that

The commission considers it is desirable that the data for the purposes of comparison should be sent to the president of the commission, South Kensington (Solar Physics Observatory), for tabulation and comparison. The commission attaches the greatest importance to this work, more especially as it may lead to a practical system of long-period forecasting, and hopes that if it be necessary, an increase of staff at that observatory may be authorised to bring all old observations up to date.

The commission, after a vote of thanks to the president, adjourned *sine die*.

The commission has circulated in the appendix to its report much valuable correspondence, but we have not space to refer to it.

With regard to the Innsbruck meeting, the following members of the commission are expected to be present:—M. A. Angot, Bureau Central Météorologique, Paris; Prof. H. J. Ångström, University, Upsala; Prof. F. H. Bigelow, Weather Bureau, Washington; Prof. Birkeland, University of Christiania; Rev. P. R. Cirera, S.J., Observatorio del Ebro, Tortosa, Spain; Dr. W. G. Davis, Oficina Meteorologica Argentina, Cordoba, Argentine Republic; M. Deslandres, Observatoire d'Astronomie Physique, Meudon, Seine et Oise; Sir John Eliot (secretary), 54 Prince of Wales Mansions, Prince of Wales Road, Battersea, and Bon Porto, Cavalaire, Var, France; Prof. G. E. Hale, 678 St. John Avenue, Pasadena, California, U.S.A.; Hofrat Prof. J. Hann, XIX Hohe Warte, Vienna; M. Janssen, Observatoire d'Astronomie Physique, Meudon, Seine et Oise; Prof. W. H. Julius, Rijks Universiteit, Utrecht, Holland; Prof. W. Köppen, Deutche Seewarte, Holland; Prof. S. P. Langley, secretary of the Smithsonian Institution, Washington; Sir Norman Lockyer (President), Solar Physics Observatory, South Kensington; Dr. W. J. S. Lockyer, Solar Physics Observatory, South Kensington; Hofrat Prof. J. M. Pernter, Hohe Warte, Vienna, Austria; Prof. Riccò, University de Catania, Sicily, Italy; Prof. G. B. Rizzo, University of Messina, Sicily, Italy; Prof. L. A. Rotch, Blue Hill Meteorological Observatory, Cambridge, Mass.; Sir Arthur Rücker, 19 Gledhow Gardens, S.W.; Prof. J. Scheiner, Königl. Friedrich Wilhelms Universität, Berlin; Dr. W. N. Shaw, Meteorological Office, 63 Victoria Street, Westminster; Prof. A. Steen, Meteorological Institute, Christiania; Prof. J. Violle, Conservatoire des Arts et Métiers, Paris; Prof. C. H. Wind, University of Utrecht, Holland; Prof. A. Woeikoff, St. Petersburg, Russia; Herrn Prof. Max Wolf, Grossherz Ruprecht-Karls Universität, Heidelberg, Germany; Prof. A. Wölfer, Zurich Observatory, Switzerland.

THE TEACHING OF PRACTICAL CHEMISTRY AND PHYSICS.[1]

DR. FISCHER has set himself the almost limitless task of describing and comparing the various methods of science teaching adopted by the principal nations of the world, but he has succeeded in collecting a good deal of useful and accurate information, which he has given in a concise and interesting form.

He deals with the present state of the teaching of physics and chemistry in Germany, Austria, Hungary, Italy, France, Sweden, Norway, Holland, Russia, Finland, Great Britain, Ireland, and the United States of America. In each instance he not only describes the methods of instruction now prevailing, but in a few words indicates the gradual way in which all branches of science are slowly but surely obtaining a recognised place in education.

The chief point dealt with in connection with the teaching of physics and chemistry is the establishment of practical classes for students in the secondary and other schools. In this Great Britain, Ireland, and America are far ahead of the other countries. In Germany, at the present time, comparatively few schools, especially in South Germany, have laboratories where the pupils themselves can carry out experiments in chemistry and physics. Where such practical work has been allowed, it has elicited much interest from the pupils, even when the classes have had

[1] Abhandlungen zur Didaktik und Philosophie der Naturwissenschaft. Heft 3. "Der naturwissenschaftliche Unterricht bei uns und im Auslande." By Dr. Karl T. Fischer. Pp. 72. Price 2 marks. Heft 4. "Wie sind die physikalischen Schülerübungen praktisch zu gestalten?" By Herr Oberlehrer Hahn. Pp. 67. Price 2 marks. (Berlin: Julius Springer, 1905.)

to be held outside the proper school-hours. At the German universities, however, laboratory instruction began relatively early, and now stands on a high level compared with other countries. In Austria, science teaching has been considerably developed, but practical classes have not yet been introduced. In Italy, laboratories for the students at the secondary schools are still unknown, but in France they have been building school laboratories for practical work throughout the country ever since the official regulations of 1902.

In Sweden, the time devoted to natural science is now being increased; scholars can, in most cases, carry out experiments in chemistry, but practical work in physics is almost unknown in the secondary schools belonging to the State. In Norway, there are no secondary school laboratories, although natural science is compulsory. Then again, in Holland, the secondary schools have no practical classes, but the study of physics there is carried further than even in Germany. In Russia, science laboratories are being introduced with considerable success. Until two years ago, physics was the only scientific subject taught in the secondary schools, but since then botany and zoology have been added. The experience gained in Russia in connection with laboratory work has been favourable, in spite of many hampering circumstances. Several recently erected school-buildings have physical departments which have been built regardless of cost; the Physical Institute at St. Petersburg has cost about a million marks, and a still larger one is being built at Moscow.

Dr. Fischer has already shown by his book, "Der naturwissenschaftliche Unterricht in England," that he has an intimate knowledge of English methods of education. His book was the outcome of a visit to this country.

In treating of the teaching of science in the United States of America, reference is made to the alterations in the curriculum of a great number of schools, necessitated by the recent regulation that previous experience in practical physics and chemistry is essential before being admitted to Harvard University and the Lawrence Scientific School.

Finally, various details relating to the universities, technical, medical, and other schools in the countries previously enumerated are given in tabular form; this clearly shows the rapid progress instruction in practical physics has made during the last thirty years. The illustrations include plans and views of laboratories in Munich, Hamburg, Rotterdam, Meppel, Alkmaar, London, &c.

Although space permits of only a very brief reference to some of the principal points dealt with, it is enough to indicate that this pamphlet can hardly fail to interest and to be of use to those who are concerned in the teaching of chemistry and physics.

The pamphlet by Herr H. Hahn, entitled "Wie sind die physikalischen Schülerübungen praktisch zu gestalten?" like that by Dr. Fischer, is one of the separate parts issued, from time to time, by the well known *Zeitschrift für den physikalischen u. chemischen Unterricht.*

Herr Hahn is undoubtedly one of the many teachers of science in Germany who are convinced that the time has now come to introduce the practical teaching of physics into all schools throughout the German Empire. He is endeavouring to attract attention to this subject by describing what has been, and is being, done in other countries, more particularly in England and America. This is probably the best way of refuting the objections of those who oppose this advance.

The first portion is devoted to suggestions as to the best methods of conducting practical physics classes in schools and to the aim of such work. It is pointed out that formerly the object was merely to impart knowledge, but that now it is to show the pupil the way he has to set about to acquire knowledge for himself, to confirm laws which are known to him, and also to discover those of which he is as yet unaware. Much rational advice is given regarding the management of practical classes; special stress is laid upon the advisability of avoiding the use of unnecessarily elaborate and expensive apparatus, and of attempting, when possible, to go back to the simple and ingenious means by which a law was first discovered by one of the great men of science. The author advocates students working singly, and argues that, as all boys, as a rule, work at about the same speed, it is possible to put the whole class at the same experiment; usually one finds, however, it is only the most elementary apparatus that can be stocked on so extensive a scale.

Various other questions are gone into, such as the writing-up of note-books in the laboratory, the supplementing of laboratory work by demonstrations, the training of teachers, &c. From the numerous extracts and foot-notes, one observes that Prof. Hahn has made a most careful and thorough digest of all the existing English and American literature bearing on this branch of science teaching.

The second part deals with laboratories and their fittings, and is illustrated with a number of drawings of fittings, small but clearly executed. These, apparently, are all taken from other books; in fact, about half of them have been reproduced from an English work—Russell's "Planning of Chemical and Physical Laboratories." After some introductory remarks on the size and arrangement of suitable rooms, a description is given of each of the fittings separately, beginning with the simple work-bench for physical laboratories in schools. The ideal is considered to be a bench made to accommodate one worker only, or two in cases of necessity, but it is pointed out that this is too extravagant of floor-space and money to be really practicable. Details of the arrangement, construction, and material of the work-benches are briefly discussed. All the other fittings usually provided are described, and some useful information is given concerning the actual room itself, schemes for heating and ventilating, the supply-pipes, &c.

Again, one notices that a diligent search has been made for English, American, and German books and papers dealing with the fitting-up of laboratories; from these much information and data have been extracted and compared. The search, however, has as usual been most unproductive; one finds in the list of literature merely some five English books and magazine articles, together with two American and three German ones.

Although only a general survey has been attempted of the arrangement and equipment of school laboratories, it would probably be difficult to find a more complete abstract on this subject, and the pamphlet contains much information which will prove useful to those who are fitting-up laboratories.

STANDARDISATION IN PHARMACY.[1]

THE principle of standardisation and its embodiment in daily practice marks the most important advance which pharmacy has witnessed within recent years. Standardisation as applied to a crude drug or a preparation is understood to imply that by a method of appropriate treatment ascertained by direct experiment it has been made to conform to a predetermined standard. The required standard may have a physical, chemical, or physiological basis, and may have reference either to one or more definite principles or to a mixture of indefinable substances. The object of standardisation is to secure uniformity of product, more especially in respect of medicinal activity. It is not necessary to hark back more than a generation to see the ever-lengthening strides which pharmacy has taken in the direction of plant analysis and the isolation of definite principles. To this fact the text-books on materia medica and lectures of twenty-five years ago bear indisputable testimony. Then the maximum of knowledge of the constituents of many of even the best known and most potent drugs was summed up in the statement that they contained a crystalline principle, generally an alkaloid, and a few remotely proximate and chemically unclassified substances. Before standardisation could be brought within the range of pharmaceutical possibility it was necessary to make a more thorough systematic and accurate investigation of crude drugs, with a view of obtaining precise information as to the nature of their constituents.

To this task the younger generation of workers in the field of pharmaceutical research have mainly directed their efforts. Latterly they have occupied themselves more

[1] Abridged from the Presidential Address delivered by Mr. W. A. H. Naylor before the British Pharmaceutical Conference at Brighton on July 25.

especially in seeking to devise trustworthy processes for the assay of crude drugs and their preparations, and to the extent to which they have succeeded they have contributed in their measure to the benefits conferred on suffering humanity by the healing art.

A few pointed observations reflecting my personal opinion on certain aspects of the question of standardisation may not, I trust, be considered inappropriate with which to conclude my address. In my estimation the aim should be to produce preparations that will represent the sum total of therapeutic activity of the drugs operated on except in cases where it is desired to obtain the medicinal effects of certain definite principles the physiological action of which is indisputable. As an illustration a preparation of opium may be cited where the presence of narcotine may be considered objectionable. Further, in respect of a given preparation it must be required of the pharmacist to devise suitable processes not only for the estimation of the chief medicinal constituent, but as far as possible the several medicinal constituents and the proportion in which they are present. I would go even further, and say that in the near future it may be necessary to determine certain principles hitherto disregarded, which modify the therapeutic activity of the drug. The pharmacologist may be depended on to point the way, and despite the heavy tax this call for fuller investigation will put upon the resources of the pharmacist, I am encouraged to believe he will prove equal to the demand. Without reflecting on modern methods of standardisation, which undoubtedly have met with general acceptance, I cannot suppress the conviction that their tendency is not free from a suspicion of narrowness. The besetting temptation consists in a disposition to restrict the medicinal properties of a drug to a potent principle, the therapeutics of which are universally recognised by clinicians, and acting on this assumption to proceed to produce a preparation and to standardise it on the basis of the particular principle and with little or no regard to other constituents that may directly or indirectly be of value. For instance, according to present-day knowledge, the chief active principle of the three drugs belladonna, scopola, and henbane is hyoscyamine. If a tincture of each be prepared so as to contain the same percentage of alkaloid or alkaloidal content, will it be seriously contended that therapeutically considered the three are interchangeable, and therefore it is a matter of indifference which of them is selected for use? If the physician finds it a distinct advantage to administer the belladonna tincture in one case and the henbane tincture in another, surely it is because he is satisfied that the two preparations do not produce identical results. May this not be taken as *primâ facie* evidence that there are in the tinctures constituents present, other than hyoscyamine or alkaloidal content, which claim to be reckoned with?

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—The senate has accepted the offer made by the Secretary of State for the Colonies of the sum of 700*l.* a year for five years for the purpose of instituting a chair of protozoology. Of this sum, 200*l.* a year is a contribution from the Rhodes trustees, and 500*l.* a year represents a moiety of a grant originally made from the tropical diseases research fund to the Royal Society for the promotion of research work, and by the Royal Society surrendered for the purpose of endowing the chair. It was decided to devote the whole amount as salary of the professor, and to set aside a further sum of 200*l.* a year to defray the cost of assistants and laboratory expenses in connection with the chair.

Mr. Edgar Schuster, the Francis Galton research Fellow in national eugenics, has presented a report containing a preliminary account of inquiries which have been made into the inheritance of disease, and especially of feeble-mindedness, deaf-mutism, and phthisis.

Of the five commissioners under the Bill promoted by the university and University College for the determination of the conditions under which the college will be incorporated in the university, which measure received the Royal assent on July 11, Lord Justice Cozens-Hardy and Sir Edward Busk were nominated by the university, and Sir John Rotton and Prof. J. Rose Bradford by the college. The remaining commissioner is to be appointed by His Majesty in Council, and will act as chairman. Sir Edward Fry, late Lord Justice of Appeal, has consented to allow his name to be submitted to His Majesty in Council for this post, and it is expected that the Order in Council announcing his appointment will shortly be published.

Under the will of the late Dr. Nathaniel Rogers, a prize of 100*l.* is offered for an essay on "The Physiology and Pathology of the Pancreas." Essays, preferably type-written or printed, must be sent to the secretary of the senate by, at latest, May 1, 1907.

THE services rendered to science by the late Dr. T. M. Drown, president of Lehigh University, are to be fittingly recognised, subscriptions having been invited for the purpose of erecting at the university a building to be called Drown Memorial Hall in his honour.

PROF. W. A. TILDEN, F.R.S., has been appointed dean of the Royal College of Science, South Kensington, in succession to Prof. J. W. Judd, C.B., F.R.S., who retired from the position on July 31.

MR. H. J. HUTCHENS has been appointed demonstrator of bacteriology in the University of Durham. He will continue his work for the Royal Commission on Tuberculosis.

THE subject of the health essay (Durham University) for 1908 is "Injuries and Diseases of the Arteries, Veins and Capillaries, and their Treatment." Essays must be typewritten or printed, and reach the professor of surgery not later than March 31 of the year for which it is to be awarded.

A REPORT on the work of University College, London, for the session 1904–5, was read by Prof. Cormack, dean of the faculty of science, at the assembly of the faculties of arts and laws and of science on July 5. The report records that the Bill for the incorporation of the college in the University of London has passed the House of Lords, and has also passed its first and second readings, as well as the committee stage, in the House of Commons. It is therefore expected that the Bill will receive the Royal assent before the end of the present Parliamentary session. In that case the commissioners, appointed under the Bill to carry out the incorporation of the college in the university, will begin their meetings after the long vacation, and it ought to be possible to complete the actual incorporation by September, 1906. Of the sum of 200,000*l.* required for this purpose, all but 17,000*l.* has been obtained. In the department of applied mathematics the most important event of the session was the generous grant by the Worshipful Company of Drapers of 400*l.* yearly for five years to continue the biometric and research work of the department. This grant has put on a more permanent footing the work already instituted by the same company two years ago. Six memoirs have been specially published as a Drapers' Research Series, and a number of others are in preparation. The work for these has been rendered possible almost entirely by the financial aid provided by this gift. The number of research papers emanating from this department is eighteen, and among them may be noted a paper on "Some Disregarded Points in the Stability of Masonry Dams," which directs attention to a number of complicated and highly important technical questions, and is a valuable contribution both to theory and practice. The research work done in the Pender laboratory during the session has included such practically important matters as :—additional improvements in means for the photometric measurement of the value of incandescent electric lamps; a long research on the magnetic qualities of alloys, not containing iron, which promises to be of great technical importance; and the invention of instruments called cymometers, which are, in effect, electrical spectroscopes, and enable the frequency of the oscillations in any electric circuit to be measured with great accuracy. Several important contributions to science have come from the department of chemistry; and the list of publications by investigators in this and other departments shows that the activity of the college in producing original work is being maintained.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 24.—M. Troost in the chair.—On the total eclipse of August 30: M. **Janssen.** Observations will be taken at Alcocebre, near Valencia, in Spain.—On a simple case from which can be easily calculated the mutual action of consecutive rings constituting a tube, and on the influence of this mutual action on the propagation of liquid waves in this tube: J. **Boussinesq.**—On the nature of the hydrocyanic glucoside of the black elder: L. **Guignard** and J. **Houdas.** The bruised leaves were macerated with water for twenty-four hours at a temperature of 25° C.; the liquid gave a distillate from which semicarbazide separated a crystalline precipitate, identical with benzaldehyde semicarbazide. This result, together with the formation of hydrocyanic acid, shows that the elder leaf contains amygdalin.—The catalytic decomposition of monochlor-derivatives of methane hydrocarbons in contact with anhydrous metallic chlorides: Paul **Sabatier** and A. **Mailhe.** The chlorides of nickel, cobalt, iron, cadmium, lead, and barium, at a temperature of about 300° C., readily decompose the fatty alkyl chlorides, giving hydrochloric acid and the corresponding ethylene. The reaction does not take place with methyl chloride, but ethyl, propyl, isobutyl, and isoamyl chlorides readily decompose under these conditions, barium chloride being the most convenient catalytic agent.—The convergence of rational fractions: H. **Padé.**—Experimental researches on the effect of membranes in liquid chains: M. **Chanoz.** The effect of the membrane on the observed electromotive force may be provisionally explained by the formation at the expense of the electrolyte of a double electric layer in contact with the membrane.—The hysteresis of magnetisation of pyrrhotine: Pierre **Weiss.**—On a dihedral stereoscope of large field, with bisecting mirror: Léon **Pigeon.**—On fluorescence: C. **Camichel.** An experimental proof that the coefficient of absorption of a fluorescent body does not vary at the moment of fluorescence, and that the intensity of the light emitted by the fluorescence is proportional to the intensity of the exciting light.—The influence of water vapour on the reduction of carbon dioxide by carbon: O. **Boudouard.** The reduction of carbon dioxide by carbon at temperatures between 650° C. and 1000° C. is practically unaffected by the presence of water vapour, the state of equilibrium being nearly identical whether the gases are dry or moist.—On an extension to oxide of zinc of a method of reproduction of silicates of potassium and other bases: A. **Duboin.**—On a sub-iodide of phosphorus and the part played by this body in the allotropic transformation of phosphorus: R. **Boulouch.** The sub-iodide is produced by the action of sunlight on a solution of iodine and phosphorus in carbon disulphide; it is formed as a precipitate, being insoluble in carbon disulphide, and has the composition P_4I. It is decomposed by dilute potash solution, losing its iodine and apparently forming P_4OH.—On a potassium iridiochloronitrite: L. **Quennessen.**—The action of sodium sulphite upon ethanal: MM. **Seyewetz** and **Bardin.** Under certain conditions, details of which are given, crotonic aldehyde is formed in this reaction, the yield (40 per cent.) being sufficiently good to make this a preparative method.—On sparteine: the hydrates of methyl-, dimethyl-, and trimethylsparteine: Charles **Moureu** and Amand **Valeur.**—On gentiine: Georges **Tanret.** Gentiine is the glucoside accompanying gentiopicrin. Hydrolysed with dilute sulphuric acid, gentienine, glucose, and xylose are formed. It is noteworthy that this is the first known glucoside which gives xylose amongst its products of hydrolysis.—The chemical equilibrium of the system: ammonia gas, isoamylamine chlorhydrate: Félix **Bidet.** Pressures are given both for the direct and inverse reaction at −23°, −9°, −5°, 0°, and 16°, the concordance between the two sets of observations being quite satisfactory.—On the regeneration of the bruised radicle: P. **Ledoux.** There is no regeneration of the parts cut, and in the case of the lateral roots there are other anatomical differences.—On the shrimps of the genus Caricyphus arising from the collections of the Prince of Monaco: H. **Coutière.**—On the growth in weight of the chicken: Mlle. M. **Stefanowska.** Curves of growth are given for both sexes; there is a point of inflection in the curves for the male when it has attained 77 per cent. of its maximum value, and for the female at 21 per cent. The results of the observations are expressed empirically in two hyperbolas.—Experiments on the mechanical washing of the blood: Ch. **Répin.**—Intra-organic combustions measured by the respiratory exchanges as affected by residence at an altitude of 4350 metres: G. **Kuss.** These observations were carried out on several subjects at the summit of Mt. Blanc. There were seven persons under experiment; they stayed at the observatory on the summit from four to ten days, their respiratory coefficients being determined several times daily. Both before and after their stay on Mt. Blanc observations were made at Chamonix (1065 metres) and at Angicourt (100 metres). The conclusions drawn from the whole of the experiments are that the respiratory exchanges are not sensibly modified by a prolonged stay at great altitudes, and a slight attack of mountain sickness is also without influence on the results.—On the presence of poison in the eggs of bees: C. **Phisalix.** The eggs of bees contain a small amount of poison of the same nature as that present in the adult bee. Each egg contains about 0·001 mgr. of the venom, and as each egg weighs about 0·15 mgr. it follows that the toxic substances present amount to about 1/150th part of its weight.—On the production of mechanical work by the adductor muscles of the Acephalæ: F. **Marceau.**—On the structure of the muscles of the mantle of cephalopods with respect to their mode of contraction: F. **Marceau.**—The germination and growth of the artificial cell: Stéphane **Leduc.**—The study of the diaphragm by means of orthodiascopy: H. **Guilleminot.**—The general movements of the atmosphere in winter: Paul **Garrigou-Lagrange.**

SOCIOLOGICAL SPECULATIONS.

A Modern Utopia. By H. G. Wells. Pp. xi+393. (London: Chapman and Hall, Ltd., 1905.) Price 7*s.* 6*d.*

IT is instructive to watch the growth, both in power and in hopefulness, of Mr. Wells's criticism of life. In the "Time Machine" his forecast of the future of humanity was frankly appalling; in "When the Sleeper Wakes," more lurid (albeit far more probable) than the worst imaginings of "reforming" socialists. "Anticipations" was a most stimulating book, but so deliberately confined itself to exalting and exaggerating the prospects of a single aspect of life, so exclusively devoted itself to glorifying mechanical and material progress, that those sensitive to our spiritual and æsthetic possibilities might be pardoned for regarding the present order, with all its cruelty, waste, sordidness, and grotesqueness, as a golden age in comparison with Mr. Wells's world. "Mankind in the Making" contained much vigorous criticism and many sensible and practical suggestions. In the present book Mr. Wells has become still more moderate and practicable and hopeful, without in the least derogating from his ingenuity and originality. We sincerely hope, therefore, he will not, as he threatens, stick henceforth to his "art or trade of imaginative writing," but will continue from time to time to regale and stimulate us with sociological speculations.

Stripping off the romantic form—in which Mr. Wells dreams himself and a companion, a botanist suffering from a chronic affair of the heart, into a distant planet which is an exact duplicate of our earth, save that it has realised all the good which is attainable with our present resources—his main argument may be condensed as follows.

As the philosophic foundation of his whole enterprise, Mr. Wells assumes what he calls the "metaphysical heresy" (though it is rapidly forcing itself upon the notice even of the most stagnantly "orthodox" philosophers) that all classifications, though convenient, are crude, and that whatever is real and valuable in the world is individual, a thesis he had expounded in the brilliant contribution to *Mind* entitled the "Scepticism of the Instrument," which he has now reprinted as an appendix to his book. From this philosophy he infers that progress depends on individual initiative and variation, leading to successful experiment. Hence the infinite preciousness of freedom, which the Utopian World-State must restrict only when and in so far as it would oppress the freedom of others. Hence, too, there will be extensive toleration of "cranks," while even criminals would merely be segregated as failures and condemned to work out their ideas of a good life in a society of their likes, after a fashion charmingly described in the account of the arrival of involuntary immigrants at the "Island of Incorrigible Cheats." But though Utopia is strangely kind to the cranky, the criminal and the inefficient, because it regards their occurrence as the measure of the State's failure, it does not allow them to reproduce their kind. Parentage is a privilege, and the production of superior offspring a service to the community for which a wise State will handsomely reward its women.

But the efficiency and prosperity of the Utopian order ultimately depend on the ruling class, which Mr. Wells seems to have taken bodily out of the Platonic Republic, and, with a fine compliment to the unparalleled rise of Japan, entitled the "Samurai." The Samurai are conceived as a "voluntary nobility" which (like the mediæval Church) all may enter who are able and willing to lead the strenuous and somewhat ascetic life prescribed by the rules of the Order. Among these the obligations to buy and read every month at least one book published in the last five years, and every year to go out into the wilderness and to travel through it in silence and solitude for at least seven days, are perhaps the most noticeable, together with the prohibition of acting, singing and reciting, and the playing of games in public.

It is remarkable how Platonic is the general spirit of these institutions in all save the high appreciation of individual freedom, to the value of which Plato showed such singular blindness. Nor is their general aim hard to discover. At several points, however, a critic will be disposed to doubt whether Mr. Wells's means are adequate to his ends. He has seen, indeed, what never seems to have occurred to Plato, that if wisdom is to control the State, elaborate precautions must be taken to keep learning progressive, and to prevent it from fossilising into pedantry. The Platonic State, if it could ever have come into existence, would systematically have suppressed originality, and simply have stereotyped the condition of science and art prevailing at the date of its institution. If it could be conceived as surviving to the present day, it would still be sending its heroic hoplites against quick-firing guns, and still be punishing a belief in evolution or metageometry as heresies worthy of death. Mr. Wells seeks to guard against the universal human tendency to fix in rigid forms whatever man admires. But though he insists on the importance of preserving the "poietic," *i.e.* originative, types of man and endowing their researches, it may be doubted whether even under his laws they would not be overpowered by the "kinetic," *i.e.* the efficient administrators, who everywhere conserve the established order. For these latter would control the Order of the Samurai.

Again, Mr. Wells's distrust of eugenics, justified as no doubt it is by the present state of our knowledge, seems unduly to disparage the prospects of scientific discovery in the future. It does not follow that because now we know too little to entrust the State with the function of controlling the reproduction of the race, this will continue to be unsafe, and it is easy to imagine circumstances in which such control would become almost inevitable. For example, if one of the many attempts to discover what determines the sex of an embryo should chance to be crowned with success, the numerical equality of the

sexes would in all probability be gravely imperilled, and the State would almost certainly have to intervene. Again, while Mr. Wells is doubtless within his rights in scoffing at the racial prejudices of the time, in his scorn of popular notions of "superior" races, "including such types as the Sussex farm labourer, the Bowery tough, the London hooligan, and the Paris apache," and in his contention that "no race is so superior as to be trusted with human charges," his anticipation of wholesale racial fusions seems to involve a serious underestimate of the æsthetic instincts. Lastly, although Mr. Wells has keenly perceived the spiritual value of a temporary retreat from society, it may be doubted whether he does not purchase its advantages at too high a cost. The solitary voyages of his Samurai would assuredly lead to a high death-rate among them, and though one type of mind was thereby strengthened, another would be unhinged. The rule, in short, seems too rigid for the variety, and too cramping for the freedom, of man, both of which Mr. Wells is elsewhere anxious to appreciate. But Mr. Wells, on the whole, shows a wisdom far superior to that of former Utopists in not seeking to construct out of the imperfect materials which alone the actual can furnish a static order which shall be, and if possible remain eternally, perfect. He aims rather at laying down the principles of an order which shall be capable of progressively growing towards perfection; and so it may well be that in his ideal society men will be less reluctant than now to learn from experience.

F. C. S. S.

THERMODYNAMICS.

Thermodynamik. By Dr. W. Voigt. Vol. ii. Pp. xii+370. (Sammulung Schubert, xlviii.) (Leipzig: G. J. Göschen, 1904.)

Diagrammes et Surfaces thermodynamiques. By J. W. Gibbs. Translated by G. Ray, of Dijon, with an introduction by B. Brunhes, of Clermont. Pp. 86. (Paris: Gauthier-Villars, 1903.)

THE second volume of "Thermodynamik" deals essentially with applications. It is divided into two parts, devoted to thermochemical changes and thermoelectric changes respectively. Under the first heading are included changes of phase of a single substance, which occupy the first 168 pages. In this connection we have sections dealing with Van der Waals's formula, steam and gas engines, the equilibrium of an atmosphere of water vapour, and the Hertzian adiabatics. The next chapter deals with phases formed of more than one component, the properties of binary mixtures occupying about 80 pages, and those of a system with more than two components being treated subsequently. The part dealing with thermoelectric changes contains a good bit of introductory matter on electrostatics. In the third chapter of this part the properties of black-body radiation are discussed at much length.

The subject of thermodynamics can be defined in various ways. In its most restricted sense it deals exclusively with the first and second laws and direct deductions from them, in just the same way that dynamics deals with direct deductions from the laws of motion. But the name thermodynamics is often used to include all phenomena directly or indirectly associated with heat, and it is in a fairly broad sense in this respect that Dr. Voigt deals with the subject. A good many of the formulæ are based more or less on experiment or reasoning not directly connected with the two laws of thermodynamics. Thus, for example, in the chapter on radiation the only piece of work which can be regarded as thermodynamical in the narrower interpretation is the proof of the equation by which Stefan's law is deduced from the formulæ for radiation pressure. But in addition to this we have here a general discussion of radiation based on electrodynamical considerations, Wien's law, Planck's law of mixture, and Kirchhoff's theorem. The relation between the black radiation and wave-length is in no way deducible directly from the first and second laws.

These examples may be taken as affording some indication of the extended scope of the book. Passing to matters of detail, the author is to be congratulated on the lucid way in which he clears up many points usually regarded as obscure. We may instance the detailed discussion of the thermodynamical potential of a gas-mixture (§ 69), a point which receives scanty attention in many books we have seen. The author's task is made easier by the fact that most of the higher applications of thermodynamics deal with *equilibrium*. Now, whether we deduce the conditions of equilibrium from making the available energy a minimum, the entropy a maximum, or by any other equivalent hypothesis, the variation of the function selected must in general vanish to the first order, so that the conditions of thermodynamic equilibrium (apart from stability) are deducible from the equations of *reversible* thermodynamics. Very little is said in this book about irreversible phenomena, and this is perhaps fortunate owing to the great difficulty of dealing with these phenomena in a clear and logical way. The kind of impression which a beginner is likely to form in reading about irreversible thermodynamics may be exemplified by the following three apparently contradictory statements:—"The increase of entropy is dQ/T." "The entropy of the universe tends to a maximum." "For a cyclic irreversible cycle $\int dQ/T<0$."

It would be hardly an exaggeration to assert that whether any statement in irreversible thermodynamics is right or wrong depends entirely on the way of looking at it. For example, in § 105 a very little is said about irreversible electric phenomena, which is doubtless correct according to the author's interpretation; but whether this is the best way of stating the case is necessarily a matter of opinion.

In connection with the continuity of the liquid and gaseous states, the rule for the horizontal line in the isothermal diagram is deduced from van der Waals's equation (p. 151), and is not treated as a general result. In this method, however, the significance of the rule is somewhat lost. The proper condition that the rule may hold good is that the liquid and gaseous

states should be connected up in the (p,v) plane by a system of curves $T=$constant, consistent with the differential equation

$$\frac{dy_v}{dv} = T\frac{d^2p}{dT^2},$$

and making y_v equal to the specific heat at constant volume in the regions which represent physically possible states. For the validity of the rule it does not matter how the curves are joined up provided that the above differential equation is everywhere satisfied.

The notation may appear somewhat cumbersome, but anyone who tries to express thermodynamical formulæ in writing will find it impossible to do so clearly and precisely without some such large array of symbols. In particular, the use of capital letters for the volume, entropy, energy, and other thermodynamic magnitudes of a whole body, and small letters for the corresponding magnitudes per unit mass, is a very useful convention. The different forms of d, δ used for differentiations, variations, and diminutions are less easy to follow. If we attempt to compare the subject of this volume with Prof. Planck's excellent little treatise, we shall probably come to the conclusion that Prof. Voigt goes more into elaborate details, while Prof. Planck keeps more to the main points. The book now before us thus contains the more information about a wide range of physical phenomena, but Prof. Planck's book is the easier to read. Neither book can be said to be better or worse than the other, as each has its own uses.

The French translation, which forms No. 22 of the physico-mathematical series appearing under the title of *Scientia,* contains the two papers "Graphic Methods in the Thermodynamics of Fluids" and "A Method of Geometric Representation of the Thermodynamic Properties of Substances by Means of Surfaces," both originally published in the Connecticut Transactions for 1873. It is accompanied by a short notice of Gibbs's life and works, and an introduction by Prof. Brunhes. The latter, giving as it does a general and explanatory account of the subject-matter of the papers translated, forms a useful addition to the book.

G. H. B.

FUNGUS-GALLS.

Beiträge zur physiologischen Anatomie der Pilzgallen. By Hermann Ritter von Guttenberg. Pp. 70; with 4 plates. (Leipzig: Wilhelm Engelmann, 1905.) Price 2s. 9d. net.

THE study of galls is never more profitably approached than when the mutual inter-reactions between parasite and host-plant are considered conjointly. The intimate connection existing between these two, whether the parasite be insect or fungus, forbids the divorce of either party, and it is therefore a pleasure to come across a work in which this close union is recognised, and an endeavour made to explain the anatomical changes occurring in fungus-galls from a physiological standpoint.

In this work the effects caused by five different fungi on as many host-plants are described. The fungi all belong to separate families, as also do the hosts, and the series is therefore admirably suited for generalising the results. It includes Albugo on Capsella, Exoascus on Alnus, Ustilago on Maize, Puccinia on Adoxa (where, however, no gall-formation arises), and Exobasidium on Rhododendron.

The constancy of form and complexity of structure, characteristic of many insect-galls, are not found here, and the principal changes observable may be briefly summarised as consisting of the hypertrophied development of a large-celled, thin-walled parenchymatous tissue containing very vacuolated protoplasm, enlarged nuclei, and rich stores of starch or water. This is accompanied by an increase in the number of vascular bundles, or at least of their elements, and by modifications of the epidermis, whilst the assimilatory and aërating systems generally tend to be suppressed.

These anatomical changes are, in the author's opinion, mostly due to a change of function which the tissues assume under the influence and for the exclusive benefit of the parasite. The fungus may almost be regarded as a sculptor working with clay. It moulds the host-plant at will, forcing it to lay down a store house and fill it with food for the tenant's use, forcing the xylem to predominate when water is needed, or the phloëm when carbohydrates are required. Where spore formation is proceeding, accessory bundles are laid down to provide the increased supplies necessary. Here the epidermis is weakened so as not to hinder the dispersal of spores, there the mechanical tissue suppressed lest the progress of the fungus be impeded, while even the chlorophyll granules, when present, work in the service of the parasite. Everywhere the story reads as if the host had become wholly subservient to the will of the parasite; but were the author now to exchange his brief and act as counsel for the host, he might equally well explain many of the changes as evidencing an intense effort put forth by the latter to overcome the former. A final summing up would then be less partial, and productive of still more valuable results.

Here and there the author *has* observed indications of this struggle, and one point to which he directs attention is of special interest, viz. the deposit of a cellulose cap or sheath around the invading haustorium or hypha, apparently for the purpose of preventing its entry. This phenomenon, which, though of frequent occurrence, is not generally known, is most remarkable in *Ustilago Maydis,* where the whole length of an intracellular hypha in its passage through a cell may become enclosed in a cellulose tube. Subsequently this tube may become irregularly thickened in parts, and then shows distinct stratification.

The observations regarding the behaviour of the nucleus—its lobed appearance, occasionally leading on to amitotic division, its participation in the formation of the above mentioned cellulose sheath, its subsequent decrease in size, the aggregation of the chromatin at the periphery, &c.—are all most interesting. Some of them need confirmation by more exact histological methods than the author seems to have employed, before his conclusions can be accepted, *e.g.*

the fate of the nucleus in the epidermal cells of *Alnus incana*, which appears very doubtful. In a few other points doubts have also arisen in the writer's mind whether certain appearances described may not have been due to imperfect fixation.

The discussion concerning the attraction which the nucleus apparently exerts on the haustoria is reverted to in the section dealing with *Puccinia Adoxae*, and the solution arrived at seems natural and satisfactory.

Space will not permit us to mention many other points of interest which the reader will find in this little book. A perusal thereof will, it is believed, repay the mycologist, who, even if he doubts a few of the facts or considers the conclusions often somewhat forced, will at all events find the subject treated from a new point of view, and will thereby gain a stimulus for his own researches.

E. R. BURDON.

OUR BOOK SHELF.

Report on the Injurious Insects and other Animals observed in the Midland Counties during 1904. By Walter E. Collinge, M.Sc. Pp. v+64. (Birmingham: Cornish Bros., 1905.)

THIS is the author's second report. It deals with injurious insects and other animals which have been forwarded to him by various correspondents in the midland counties during 1904.

The work is not bulky, but contains in its sixty-nine pages a great amount of valuable matter, covering a wide ground. Its value is enhanced by twenty-nine illustrations; many of these are those used in the Board of Agriculture leaflets, and some could certainly be improved on, such as Fig. 17, the winter moth, and Fig. 22, the codling moth. The original illustrations are excellent, including those of the goat moth, the birch gall mite, crane flies, and yellow underwing larvæ. Among the most interesting notes are those on a supposed new apple mite (Eriophyes, sp.) and on carnivorous slugs.

With regard to the latter, the author tells us that living specimens have been introduced into greenhouses and nursery gardens with very beneficial results. This kind of work is most valuable, and we hope Mr. Collinge will have a larger supply to dispose of among nurserymen in future.

There is a detailed and able account of the pear midge (pp. 42–49), but amongst the supposed remedial measures we find it recommended "to deeply trench the ground beneath the trees." This has probably crept in by error. The goat moth is treated in a short, concise manner, and this paper is excellently illustrated with photographs.

Amongst other fruit pests that the author has had reported from the midlands may be mentioned the apple blossom weevil, codling moth, the plum bark beetle, winter moth, the currant clearwing, magpie moth, and, needless to say, one of the most serious pests in Herefordshire, the apple sucker. A few short notes are also given on parasitic diseases of animals, such as scaly leg in fowls, gapes in poultry, and the pig louse.

In the appendix the use and employment of hydrocyanic acid gas and bisulphide of carbon are dealt with, and a general account of insects and the classification briefly referred to. The author divides the Hexapoda into fourteen orders.

As this report should fall into the hands of practical men, we regret to see new generic names are given in the text. Scientific names have rather a frightening effect, and when we keep changing them it makes matters worse. Probably it would be better if we kept to popular names only in the text of such reports, and referred the reader to the scientific names in an appendix. The farmer and gardener want these matters put before them in as simple a way as possible.

We look forward to another of these reports with pleasure, and hope they will appear annually for the benefit of grower and economic zoologist alike, for the contents of the pages of the one before us are both scientifically accurate and preeminently practical.

F. V. T.

Studies of the Museums and Kindred Institutions of New York City, Albany, Buffalo, and Chicago, with Notes on some European Institutions. By A. B. Meyer. *Rep. U.S. Nat. Mus.* for 1903. Pp. 311–608; plates. (Washington, 1905.)

DR. MEYER'S valuable notes and comments on the museums of America and Europe are already familiar to our readers by the notices published in our columns of the issues of the original German text. Of that text the present volume is a translation, revised by the author himself, and with all the original illustrations reproduced, although in some instances on a smaller scale. Since the author's tour of inspection was primarily undertaken for the purpose of learning all that was to be learnt from American museums, the consideration of which occupies by far the greater portion of the report, it was only right and proper that an English translation of the latter should be issued in America rather than in this country, and the Smithsonian Institution deserves the thanks of all interested in museums for the excellent manner in which it has carried out its self-imposed task.

The translation will indeed be fully as acceptable in England as it can be in America, for Dr. Meyer is an outspoken critic who does not mince his opinions, and some of his views with regard to the organisation, installation, and conservancy of museums in this country cannot fail, from this same outspoken and candid manner, to have a permanent value.

Especially important are his opinions with regard to the deteriorating effect of light on the collections of recent zoology in the Natural History Museum in Cromwell Road.

"Everywhere in England," he writes, "the collections are exhibited during the entire day, and it is said that this custom must continue, otherwise the money for expenses will not be forthcoming. I think, however, that this is an error. If the officials themselves were only convinced that the collections intrusted to their keeping are really being injured, they would be able to impress this fact upon the trustees. . . . The public would soon become accustomed to shorter hours of opening if there were some way of making them generally known." Would they?

Whether or no we accept all the author's views and criticisms, there can be no doubt that the issue of an edition of Dr. Meyer's "museum survey" in English is a matter for all-round satisfaction. R. L.

Notes on Assaying and Metallurgical Laboratory Experiments. By Prof. Richard W. Lodge. Pp. viii+287. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 12s. 6d. net.

PROF. LODGE has brought together in this book the notes which have been in use for many years by the third-year students in assaying at the Massachusetts Institute of Technology and part of the notes given to fourth-year students. The book may therefore be

taken as representing the teaching given to metallurgical students in America, and forms an interesting study to those who wish to know something of the much-praised methods in vogue there. Judging from the contents of Prof. Lodge's volume, the methods do not differ much from those in use in this country and in other parts of the world. The assaying of gold and silver ores is dealt with adequately, and there is an interesting though incomplete chapter on the metals of the platinum group, but the rest of the third-year work (the assay of bullion and of copper and tin ores) is scrappy and of little value. The notes for the fourth-year's work would also not be of much help to students. For example, in the section on cleaning mercury, the student is recommended to wash away soluble and light material with a stream of water, and then to "decant off water and add a small piece of potassium cyanide (poison), which ought to clean it nicely." The author seems to have some misgivings as to whether base metals would really be removed in this way, but the true nature of the problem is nowhere stated, nor are the correct methods of purification described.

In the more valuable part of the book, the assaying of gold and silver ores is discussed at considerable length. The following differences between the instructions given to the student and those usually given in England are noteworthy:—(1) In scorification the slags are not cleaned by the addition of carbon after the eye of lead is closed. (2) In cupellation, the formation of feathers of litharge is strongly insisted on. (3) Beads from gold ores are parted by boiling three times in nitric acid of different strengths.

A large number of exact experiments in assaying are described, and inferences drawn from them. Such work is always useful, but it is better not to put it before students until it has been discussed. Some of the inferences given can hardly be accepted, such, for example, as that the presence of silver does not diminish and that of copper does not increase the cupellation loss of gold. A word of protest may be uttered against the low standard of draughtsmanship in the illustrations. The scorifying tongs, depicted twice, on pp. 13 and 38, are absolutely startling.

T. K. R.

The Practical Photographer. Library Series. Edited by Rev. F. C. Lambert. No. 18, *Gum-bichromate Printing.* Pp. xxiv+64. No. 19, *Floral Photography.* Pp. xx+64. No. 20, *Portraiture.* Pp. xxviii+64. No. 21, *Orthochromatic Photography.* Pp. xx+64. No. 22, *Figure Studies, Groups and Genre.* Pp. xx+64. No. 23, *Summer Number.* Pp. 64. (London: Hodder and Stoughton, 1905.) Price 1s. net each.

THE reputation of this excellent series of photographic books is well maintained in the above-named additions to this useful library. As in previous issues, each volume is the work of numerous authors, and the value of the series is that the information is given by those who are at work at the various subjects, and therefore more practical than theoretical.

The illustrations, which are very numerous in each number, are all of a high order of efficiency, and add greatly to the value and utility of the text. The editor in each case contributes an interesting article on the pictorial work of some photographer of note, and those included in these numbers are, in the order of the books given above:—Charles Moss, Mrs. Cadby, Furley Lewis, Harold Baker, William Rawlings, and F. J. Mortimer. An important feature of each of these essays is the reproduction of specimens of their work. As practical handbooks these new volumes will be found very serviceable.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Exploration of the Indian Ocean.

MR. STANLEY GARDINER, leader of the Sladen Trust Expedition for the exploration of the Indian Ocean between Ceylon and the Seychelles, in H.M.S. *Sealark*, has sent me the following short account of the progress of the expedition up to the date of writing. The letter is written from the Salomon Atoll, Chagos Group, and is dated June 4.

A. SEDGWICK.

Trinity College, Cambridge, August 4.

"We came on board H.M.S. *Sealark* on May 8 at Colombo. Weighing anchor the following evening we set a course for Peros Banhos, the large N.W. atoll of this group, but on the second day out appreciated the fact that we were getting in for the commencement of the burst of the S.W. monsoon. On May 14 we had reached a latitude south of the Maldives, and commenced sounding in view of the possible existence of a bank between this group and the Chagos as indicated by the soundings taken by the German *Valdivia* Expedition. I may say at once that our soundings showed a depth of more than 2000 fathoms between the two groups. The depth increases from the Maldives and Chagos towards the centre of the passage between, but in this position there would seem to be a broad flat, extending along the line of latitude with a depth of 2000 to 2150 fathoms. Of course both east and west the depth probably increases gradually to 25,000 fathoms or even more, but one obviously cannot build up any views of a possible former connection of the Maldive and Chagos Banks on such a slender basis.

"On our way down we took samples of the sea-water and of the plankton (pelagic fauna) at the surface and at every 25 fathoms to 150 fathoms, using a wire with a heavy weight at the end running over a measuring block and clamping on the nets as each 25 fathoms ran out. We also took a series of hauls with the Fowler and Wolfenden closing nets, so as to get our wire into trim, &c. The weather was dead calm with a moderate swell, and generally our results were satisfactory. The Fowler net, being opened at a certain depth and then hauled up vertically to a lesser depth and closed, seemed more suitable for the conditions prevailing in this region than the Wolfenden, which is opened and closed at the same depth, being dependent on the drift of the ship, in the absence of any deep-sea current, for what enters the actual net; heavy messengers, too, are essential for opening and closing the nets. Of course these results on the depth of pelagic animals have a value of their own, but our best haul from a collector's point of view was that of a large net, mouth one yard square, length about twelve yards, made of strong mosquito cloth, ten meshes to the inch. This net we let down on 1200 fathoms of wire and hauled in as fast as our winch could take it. Unfortunately the wire became tied up most abominably, but the comparison of the contents of the tin with the collections made by the Fowler net showed that the net itself must have actually sunk to 600 or 700 fathoms. The presence in the tin of a series of prawns (one 6 inches long), a cuttle fish, and many strong swimming jelly-fish suggests that the use of this method of investigating the swimming fauna (nekton) of the sea should yield valuable results.

"On May 19 we anchored at Île de Diamant, Peros Banhos Atoll, but it became obvious in the next couple of days that in the S.E. trade winds now prevailing in this region, any thorough examination of this atoll, open as it is to the S.E., would be impossible. Accordingly we moved on to the Salomon Atoll on May 22, coming on shore to camp on the following day, selecting it as being of small size (5 miles long by 3½ broad) and enclosed on all sides, save for one passage to the north, by a surface reef. While Cooper and I are collecting the marine fauna and flora, and examining the reefs and land, Captain Somerville and the officers of H.M.S. *Sealark* are making a fresh chart of the atoll on a large scale,

while Mr. Fletcher, paymaster, and Dr. Simpson are collecting the insects and land plants. I may say at once that the latter are of the type which one would expect to find on purely oceanic islands, but their distribution from island to island is interesting, as well as their preferences for sand or rock, drought or moisture, &c., most of the islands having definite zones with their peculiar plants.

"It is really as yet too early to say anything about the reefs here, as there are one or two places which I have not yet been able to visit. What strikes one, however, very forcibly is the comparative absence of life on them. Of course there are in places plenty of corals, but the number of species is quite limited. There is a fair number of the usual Alcyonaria, but Sponges, Hydroids, and Tunicates are very few in species and in quantity. Turbellaria are very rare, while Molluscs, Echinoderms, and Crustacea are few in species and, except certain common forms, not numerous. Ptychodera we have obtained, as well as a few Sipunculids, but Amphioxus and Thalassema we have not found. At Minikoi in two tides I have brought to the camp as great a variety of animals as Cooper and I have obtained here working ten tides up to the present. Indeed, life here is strictly limited in variety, and, when the marine collections have been fully worked up, one is inclined to anticipate, even so early, that some definite light will be thrown on the distance to which the larvæ of marine animals can cross the open ocean, on the distribution, in fact, of marine animals. The same, too, is true as well of the marine plants, nullipores alone being common.

"I am now endeavouring to work up the physical conditions of the atoll so as to find, if possible, whether there is any physical cause for the comparative paucity of free-living animals. I am sending Cooper in the ship tomorrow to Diego Garcia, where he will have four or five days while she is coaling to examine the land and reefs. I remain here, but I hope by the time of his return, in about twelve days, to have finished my work and to move on to Peros Banhos, while the *Sealark* is sounding between the banks and round the Chagos Archipelago."

The Problem of the Random Walk.

I HAVE to thank several correspondents for assistance in this matter. Mr. G. J. Bennett finds that my case of $n=3$ can really be solved by elliptic integrals, and, of course, Lord Rayleigh's solution for n very large is most valuable, and may very probably suffice for the purposes I have immediately in view. I ought to have known it, but my reading of late years has drifted into other channels, and one does not expect to find the first stage in a biometric problem provided in a memoir on sound. From the purely mathematical standpoint, it would still be very interesting to have a solution for n comparatively small. The sections through the axis of Lord Rayleigh's frequency surface for n large are simply the "cocked hat" or normal curve of errors type; for $n=2$ or 3 they do not resemble this form at all. For $n=2$, for example, the sections are of the form of a double U, thus UU, the whole being symmetrical about the centre vertical corresponding to $r=0$, but each U itself being asymmetrical. The system has three vertical asymptotes. It would be interesting to see how the multiplicity of types for n small passes over into the normal curve of errors when n is made large.

The lesson of Lord Rayleigh's solution is that in open country the most probable place to find a drunken man who is at all capable of keeping on his feet is somewhere near his starting point! KARL PEARSON.

Proposed Magnetic and Allied Observations during the Total Solar Eclipse on August 30.

IN response to my appeal for simultaneous magnetic and allied observations during the coming total solar eclipse, cooperative work will be conducted at stations distributed practically along the entire belt of totality and also at outside stations, nearly every civilised nation participating.

These observations will afford a splendid opportunity for further testing the results already obtained. All those who are able to cooperate are invited to participate in this important work.

The scheme of work proposed embraces the following:—

(1) Simultaneous magnetic observations of any or all of the elements according to instruments at the observer's disposal, every minute from August 29, 22h., to August 30, 4h., Greenwich mean astronomical time.

[To ensure the highest degree of accuracy attainable, the observer should begin work early enough to have everything in complete readiness in proper time. See precautions taken in previous eclipse work as explained in the journal *Terrestrial Magnetism* (vol. v., p. 146, and vol. vii., p. 16). It is essential, as shown by past experience, that the same observer make the readings throughout the entire interval.]

(2) At magnetic observatories, all necessary precautions should be taken so that the self-recording instruments will be in good operation, not only during the proposed interval, but also for some time before and after, and eye readings should be taken in addition wherever it be convenient.

[It is recommended that, in general, the magnetographs be run on the usual speed throughout the interval, and that, if a change in the recording speed be made, every precaution possible be taken to guard against instrumental changes likely to affect the continuity of the base lines.]

(3) Atmospheric electricity observations should be made to the extent possible by the observer's equipment and personnel at his disposal.

(4) Meteorological observations in accordance with the observer's equipment should be made at convenient periods (as short as possible) throughout the interval. It is suggested that, at least, temperatures be read every fifth minute (directly after the magnetic reading for that minute).

(5) Observers in the belt of totality are requested to take the magnetic reading every fifteen seconds during the time of totality, and to read temperatures as frequently as possible.

(6) At those stations where the normal diurnal variation cannot be obtained from self-recording instruments, it is desirable to make the necessary observations for this purpose on as many days as possible before and after the day of the eclipse, and to extend the interval of observations given above if conditions permit. In general, those who will have self-recording instruments have decided to run them for at least eight days before and after the day of the eclipse.

It is hoped that observers will send full reports of their work to me as soon as possible for incorporation in the complete monograph on this subject to be published by the Carnegie Institution of Washington.

British Fruit Growing.

IN your remarks on p. 297 (July 27) on the above subject, you mention "the diversity of yield from farms in the same neighbourhood . . . due presumably to differences of shelter and aspect." It is a remarkable thing that, so far as I know, nothing has ever been done to find out and publish the most suitable localities, as regards soil and climate, for orchard planting. It is a question of very great complexity, and can only be dealt with properly by officials appointed for that purpose; but its importance in fruit culture is so obvious that a considerable expenditure would be well repaid. Few people have any idea of the great climatic differences in localities within even a few hundreds of yards!

This house is on the south slope of the long range of Lower Greensand hills which runs parallel with the Chalk range the whole length of Kent from west to east. At this point the slope rises steeply from 200 feet above sea-level to 500 feet, my house being about 350 feet. I have carefully observed the effects of frost, &c., for the last six years, and it appears to me that the variations in temperature in the vertical limits mentioned are much greater than would be expected. Up to the 400-feet contour line the climate is singularly equable, which is proved not only by daily thermometrical observations, but by the

fact that such tender plants as *Cistus purpureus*, Lam., *Cheiranthus mutabilis*, L'Hérit., and many others have survived the last six winters unprotected; while large bushes of Laurustinus, *Euonymus japonicus*, bay, &c., were evidently little, if at all, injured by the terrible winter of 1895. Yet, even within the limits of my own grounds, with a rise of only 35 feet up to the 400-feet contour line, there is a marked difference of climate. On November 27, 1904, in the upper part of the garden, dahlias planted within 4 feet of a high wall facing south were blackened by frost, while in the lower garden those in the open border were uninjured.

The difference between the climate of this place and the Public Gardens at Maidstone is fairly shown by the following comparative statement, the temperatures from the latter having been taken when I chanced to pass the place where they are put up, and therefore not selected :—

May 11, 1904	Max. in shade	Min. in shade	Min. on grass	Range in shade
Ulcombe ...	50°·0	39°·5	35°·5 (corrected)	10°·5
Maidstone	56·0	38·0	30·0	18·0
May 28 to 30, 1905				
Ulcombe, 28th	67·6	47·5	43·8	20·1
,, 29th	70·6	57·0	44·5	13·6
,, 30th	76·0	52·0	48·0	24·0
Maidstone, 28th	76·0	43·0	39·0	37·0
,, 29th	81·0	50·0	42·0	39·0
,, 30th	85·0	50·0	42·0	43·0

The maxima in both cases are those of the previous day. Maidstone is seven miles from here, and lies in the valley of the Medway.

Yet, in spite of the fact that the thermometer, even on the grass, has not been below 32° since April 3,[1] we are no better off for apples than our neighbours! The apples did not begin to flower until the end of April, so some other cause than frost must be found to account for the bad crop. This is an example of the difficulties of the question; other complications are the nature, mechanical and chemical, of the soil; period of blooming of different varieties of the same fruit; shelter from the generally prevailing cold winds in spring; &c. Still, some effort should be made to ascertain the conditions under which, on an average of years, the best crops can be obtained, and so avoid the waste of time, money, and land that has been incurred in hundreds of instances by planting orchards in unsuitable localities, while hundreds of acres of suitable land are used for corn and other crops that would grow as well elsewhere.

ALFRED O. WALKER.

Ulcombe Place, near Maidstone.

Islands for Weather Forecasting Purposes.

IN NATURE for June 1 is a very suggestive article by Dr. Lockyer under the above heading, in which specific reference is made to the meteorology of Western Australia. It is becoming increasingly evident that the Indian Ocean and its neighbouring continents form one of the most interesting fields in the world for the study of meteorology, and as the officer-in-charge of an important section of this region I am most anxious to assist in this study in any way possible. Our progress will be slow if we start with incorrect theories, and my present object is to point out the probable inaccuracy of a few of the fundamental concepts, and to indicate briefly a few of the observed facts which seem to have a bearing upon the whole matter.

There is little or no rain in Perth of a monsoonal character. The wettest months are May, June, July, and August, during which time the prevailing winds are *not* from the S. or S.W. Rain is almost always associated with the passage of a "low" along the south coast, setting in with the wind at N. or N.W., and *finishing* when the wind veers to S.W. and S.

There is a tendency throughout the year for the winds to alternate from the eastward during the forenoon to the S. or S.W. in the afternoon. This is most marked in the summer months, when the prevailing feature of the weather map is a "high" stretching along the ocean *south* of our coastline. How far south or west this extends I cannot say. The prevalence of southerly winds in the summer time is probably due to this anticyclonic area, and Fig. 2 on p. 111 is therefore somewhat misleading.

As the sun moves north the high pressure follows it, and in June and July forms a belt across the centre of Australia. It is, however, constantly on the move from west to east. A "high" will generally during these months strike the west coast about, or to the north of, Perth, and gradually work across to the eastern States. As it passes our wind sets in strongly from the eastward, gradually veering more northerly. By the time the "high" reaches, say, Adelaide, our wind is N.N.E., the isobars are running nearly parallel to the west coast, and we are looking out for a "low" to approach from the ocean. As a general rule, the "low" is first heralded from Cape Leeuwin, the extreme S.W. corner of Australia, but rain sets in with a N. and N.W. wind all along our west coast as far as the N.W. cape. It is heaviest in the extreme S.W. The "low" generally passes south of Cape Leeuwin and across the bight to Tasmania. So long as our wind, and especially that at the Leeuwin, has any *northerly* component, we are pretty certain to have more rain, but as soon as it reaches W.S.W., and especially S.W., we anticipate clearing weather.

Whence these "lows" come before they reach us is therefore a question of great importance. I believe the usual theory upon this point is incorrect. That is, that these "lows" are northerly extensions of the Antarctic low-pressure belt, which sweep past the Cape of Good Hope, and after the lapse of a few days reach Cape Leeuwin, and so travel along the south coast of Australia. I think this is incorrect for several reasons. In the first place, I have endeavoured to trace notable storms either forward from the Cape to Australia, or backwards from Australia to the Cape, and have not been able to find any connection whatever. Secondly, from theoretical considerations, a rotating body of air in the latitude of the Cape would possess a sufficient southerly component to its motion of translation to carry it well south of Australia. Thirdly, the more direct evidence stated in the next paragraphs.

During the summer months, January, February, and March, there is a class of storm which strikes our N.W. coast and then travels across the State in a S. or S.S.E. direction, emerging in the Great Australian Bight, and travelling thence in an E.S.E. or S.E. direction towards Tasmania. Before striking the N.W. coast it can sometimes be traced from the extreme north of the State moving towards the S.W., down the coast, but keeping well out to sea, then gradually recurving, and striking the coast about lat. 20°. The existence of this class of storm and its approximate path is now beyond doubt, though until recently it was ignored in practical Australian meteorology. I think, however, it would now be safe to say that it dominates the weather of at least the western and southern portions of Australia during the summer months, though on account of the paucity of stations in its track our knowledge of the various conditions is at present elementary. It is important to bear in mind that the study of Western Australian meteorology is in its infancy. Not until the last few years was the importance of this class of disturbance recognised, and therefore any theories which had been formed require to be modified. During the last two years evidence seems to me to be accumulating that this particular class of storm persists throughout the year, and is, in fact, the dominating influence in Australian meteorology. If this be so, it can easily be seen how profoundly older theories are affected, and how necessary it becomes to make a fresh start.

Even during the summer the disturbances do not all follow along the same track. Sometimes they strike the coast near or even south of the N.W. cape, and occasionally they just miss the coast, but can be traced, following it down, but keeping out to sea, and eventually rounding Cape Leeuwin and behaving like an ordinary winter storm. It is this latter path to which I wish to direct special attention.

In the winter, as a general rule, the first intimation of an approaching "low" is obtained from Cape Leeuwin,

[1] Yet severe frost with great damage to crops in the Dartford, Rochester, and Hoo districts; also at Maidstone and Sevenoaks on May 22–3, is reported in the *Kent Messenger* of May 27.

and the storm centre invariably passes to the south of that spot. It was but natural, therefore, to suppose that the storm came from the W. or W.S.W. of the Leeuwin, and the winter and summer disturbances have been regarded as two distinct varieties. Within the last two years, however, circumstances have been noted which seem to show that there is no real distinction between the two. In July, 1904, I first directed public attention to the fact that certain of our winter storms could be distinctly traced *down* the west coast, affecting N.W. districts first, and then travelling in a S. or S.S.E. direction. I have gone somewhat fully into this matter in my "notes" on the climate of Western Australia for the month of July, 1904, and when once the fact has been indicated it becomes easy to find numbers of cases when winter storms can be seen to have a considerable southerly component of motion. Only a few days ago, for instance, a disturbance struck the N.W. coast in about lat. 20°, and travelled in a S.E. direction across the State, giving rain just along the fringe of our most eastern settlements, probably much heavier in the interior desert, and causing a heavy downpour in South Australia from the centre to the south coast. Again on May 20 a disturbance approached the N.W. cape, causing rain there, next day being definitely located in the ocean a little to the S.W. of Perth, and certainly considerably north of Cape Leeuwin, then continued to travel down the coast, rounded the Leeuwin, and behaved thenceforward just like any other winter disturbance.

There is, therefore, plenty of evidence that "lows" do travel down the Indian Ocean, even in the winter months, in a southerly or S.E. direction towards Cape Leeuwin, and probably all, or nearly all, of our storms come in this way. If this be so, the charts on p. 111 are misleading. Our rain certainly does not come mainly with a S.W. or S. wind, nor is there (probably) any stationary "high" as marked. Instead there is a series of "highs" moving towards our west coast, broken up by a series of "lows," which pass between and make for the extreme S.W. corner of Australia. The weather which we specially desire to predict comes with these "lows." Several things follow from this. One is that the Amsterdam and St. Paul Islands are far too much to the southward to be of any use to us for practical forecasting purposes, though a few years' records from there would be exceedingly valuable. Another is that Dr. Lockyer's theory about the S.E. trades and S.W. monsoon requires some modification, though it is very probable that the Indian and Australian weathers are inter-dependent and require to be studied together. A third is that Sir John Eliot's proposal for an Empire study of meteorology ought to be acted upon as soon as possible, and all our observations coordinated to some definite purpose. A fourth is that, failing this, Australian meteorologists ought to make every effort to bring about the establishment of a central Australian bureau for the study of scientific meteorology, as recommended at the recent conference held in Adelaide.

W. ERNEST COOKE.

Perth Observatory, Western Australia, July 3.

DUTY-FREE ALCOHOL.

HOW far the trade in synthetic colours and fine chemicals has been lost to the country through the heavy customs restrictions placed upon the use of alcohol is a question which has been agitating manufacturers for many years past. On the one hand, we are told that the entire chemical trade has been diverted from our shores because of the high cost of alcohol; on the other, that the alcohol question has very little to do with the matter. After the agitation for the use of duty-free alcohol had been going on for some years, and owing to its increasing intensity and to the pertinacity of a few, the Government in the autumn of last year appointed a departmental committee to take evidence in order to find out whether the high duty on alcohol really was the factor which caused the practical extinction of the aniline dye industry and accounted for our inability to found an industry in fine synthetical products. The committee commenced to take evidence on November 8, 1904, and finished on February 17 of this year.

More is heard about the loss of the synthetic colour trade to the country than about the loss of any other industry, or about the failure to establish new industries which flourish on Continental or American soil. The loss of the coal-tar colour industry is variously ascribed to incompetence on the part of our manufacturers and their failure to realise the importance of employing—and paying for—highly trained scientific chemists, to our patent laws, to trade protection abroad, and to the excessive duty charged upon alcohol in this country. The report with which we are at present dealing has to do with the last question—duty-free alcohol. A careful perusal of the questions to, and the answers of the witnesses before the commission, which included most of the well-known names in the coal-tar colour industry in this country, does not convince one that this special industry has been lost to the country owing to the high cost of alcohol.

The amount of alcohol used at the present day for preparing the dyes is not very large. At one time many of the dyes were sold as alcoholic extracts, and alcohol was somewhat largely used in the preparation of the products. Since the introduction of the azo dyes, however, alcohol is not nearly so largely employed as formerly. There are, indeed, certain dyes in which the methyl or ethyl radical is introduced during the process of manufacture, and these require the employment of methyl or ethyl alcohol in their preparation, and, of course, in this case the alcohol cannot be recovered; for example, the dyes in which dimethyl aniline is the starting product. British manufacturers who desire to make these colours import all the dimethyl or diethyl aniline from abroad. It came out, however, in the evidence that one large aniline dye company which desired to manufacture dimethyl aniline obtained Government sanction to employ methyl alcohol mixed with one-twentieth of 1 per cent. of mineral naphtha—"a condition which the company stated would suit their purposes." Although from the evidence before the commission it appeared that there was "a substantial profit to be made upon the manufacture of dimethyl aniline," for some reason or other it was never manufactured.

Reviewing the evidence of the different persons connected with the coal-tar dye industry, one is brought to the conclusion that, although the high price of alcohol has militated against the success of the industry, yet there are other even more potent factors which have prevented the industry being successful. Manufacturers, with a few isolated exceptions, have not even been successful in meeting Continental competition in dyes which do not require the use of alcohol. Prof. Green probably came very close to the truth when he said, in reply to a question as to what he considered the cause of the decline of the coal-tar colour industry:—

"They (the manufacturers) did not realise the great importance of research; the great importance of theory. They expected to see an immediate result from experiments, and if they did not get an immediate result they considered that they were wasting their money. They did not employ a sufficient number of research chemists, and they did not pay those research chemists they had to encourage them to remain. . . . There may be other contributory causes, such as the patent laws and this question of the spirit."

There seems to be a strong consensus of opinion that in the xylonite and gunpowder manufactory leave to use pure alcohol is much to be desired. Xylonite when made with methylated spirit is inclined to darken, and there is thus a difficulty in

making materials which should be white or ivory coloured.

In the gunpowder manufactory, if pure alcohol were used to dehydrate the material the dangerous drying process by heat could be done away with, because the material moistened with alcohol can be directly placed in the mixers containing acetone, &c., the moistness due to alcohol not interfering with the process of manufacture, whereas that due to water is harmful. For making so-called "condensed" powders which are totally dissolved in the solvent the action of methylated spirit is objectionable; as one of the witnesses stated, "you cannot control the surface of the grain with a methylated-ether mixture in the same way that you can with a pure alcohol-ether." To a large extent the lack of initiative on the part of British powder manufacturers may be indirectly attributed to the high cost of alcohol. Some lacquer manufacturers and users of lacquers state that lacquers made from pure alcohol are very much superior to those made from methylated spirit. Mr. Bagley, the witness from Messrs. Samuel Heath and Sons, the largest brass-founders in the world, stated that, although they are easily able to compete with Continental manufacturers so far as their brass ware is concerned, their goods are often not acceptable because of the want of durability and finish of the lacquering. The lacquer costs something about 4*s.* per gallon, but they can, by paying 32*s.*, obtain a lacquer made with absolute alcohol, and this is as good as the best foreign lacquer. The witness said he was ashamed to have to confess that they could not obtain the fine finish which the Germans produced, and, as regards the French importers, they absolutely refused to take lacquered articles, but bought them unlacquered and finished them themselves. This witness was of the opinion that the foreign lacquers were made with pure alcohol, but it was subsequently pointed out by the chairman that even abroad it was denatured. On the other hand, Mr. Gardiner, the manager of the firm of Messrs. A. Lambley and Sons, said that they not only could make lacquers as good as Continental manufacturers, but that they had a large export trade and had no difficulty in meeting Continental competition; they very rarely used pure alcohol for making lacquers.

From the extremely contradictory evidence of these two witnesses it would appear that it is more a matter of method or knack in the manufacture than of methylated or pure alcohol which determines the quality of the lacquers.

There seems very little doubt but that the manufacture of fine chemicals and synthetic perfumes is considerably interfered with owing to the British manufacturer not being able to use duty-free alcohol. When methylated alcohol is employed for crystallising the substances there is invariably a peculiar and disagreeable odour attending the finished product. But if the manufacturer, in order to get over this difficulty, employs duty-paid absolute alcohol, the increased cost of manufacture is prohibitive. It was stated in evidence, for example, that with regard to the manufacture of phenacetin "the duty on the spirit would come to 140*l.* on 100*l.* worth of the article as imported."

Chloral hydrate is another substance which cannot profitably be made in this country. In the manufacture of ether from methylated spirit Mr. David Howard stated that "if we might have pure methyl alcohol and pure ethyl alcohol, it would be a beautiful thing to make ether of. But the result of the ketones and other bodies in it is that the sulphuric acid gets in a most horrible mess, and we get abominable compounds which I have never been able to excite the interest of any chemist in yet; but they are a very great disadvantage."

Those connected with the motor-car industry and the use of alcohol for motor engines in place of petrol seemed to consider that very much better results can be obtained with pure alcohol than with methylated spirit. A perusal of the evidence leads to the conclusion that further experimenting in this direction would be advisable. One is certainly inclined to the opinion that the presence of bases would be harmful, as these would probably on combustion be converted into products which would corrode the metal work. Of course, if alcohol is to be employed for motor purposes it would of necessity require to be denatured, because it would then be sold in large and small quantities at every little oil-shop in the kingdom. If motor-engineers wish to build alcohol engines they will have to experiment with all sorts of denaturants, and, doubtless, the excise authorities would aid them in their endeavours.

In reading through the report one is struck by the repeated reference which is made to the relative cost of pure *duty-free* alcohol in the United Kingdom and in Germany; British manufacturers do not seem able to compete in the manufacture of alcohol with their German rivals even when working under equal conditions. Further, it is a well-known fact amongst chemists that it is practically impossible to get really good absolute alcohol of British manufacture. It is a remarkable fact that traces of impurities which one can barely find by analysis interfere very much with the smooth working of reactions in which alcohol is employed. This fact came out again and again in the evidence of witnesses before the committee. Those on the committee who were there to look after the interests of the excise endeavoured with great skill to shake the evidence on this point, explaining that if the quantity of an impurity was only a fraction of a per cent., it surely could not possibly cause all the mischief attributed to it. The invariable reply was, the product when made with absolute alcohol has such and such properties, but it is either impossible or a matter of extreme difficulty to obtain the same results with methylated spirit.

On the other hand, in a good many cases it appeared that sufficient experimental work had not been tried. Methylated spirit had been condemned for manufacturing this or that article, but little or no attempt seemed to have been made to try spirit denatured in other ways or to try the use of other solvents. By the Act of 1902 manufacturers were allowed to suggest other means of denaturing the alcohol, and in some cases at least the excise authorities had been very willing to aid them in their efforts. As a matter of fact, in manufacturing operations in Germany it is rare for absolute alcohol to be employed, the alcohol generally being denatured in a way which suits the particular manufacturer. Of course, where the use of pure alcohol is absolutely necessary the German has a much lower excise duty to compete with than the British manufacturer. That excise restrictions, the high duty on alcohol, and a considerable amount of red tape have, in some cases, made the manufacture of certain products—so as to compete with the foreign manufacturer—almost an impossibility there can be no doubt. But why that should hinder British manufacturers who manufacture products in which alcohol is not employed it is not easy to see.

If instead of calling in an outside "expert" (?) when an emergency arises the manufacturers were to employ a certain number of well-trained chemists, men who, after being on the staff for a short time, should be far and away superior to outside experts, there is but little doubt that fewer emergencies would

arise and that a progressive and ever-improving concern would be the result. There was a great deal in what Dr. Nichols said in his presidential address to the Society of Chemical Industry—the quotation is from memory—"Never put up duplicate plant; no plant is so perfect that it cannot be improved; after a plant has been in use a short time certain points in which it may be improved are sure to be discovered."

So if we are to compete with foreign competition no process should be worked year after year by rule of thumb, otherwise manufacturers will find their product being pushed out of the market by a similar but improved product in which the brain has been the motive power for the thumb.

It is very much to be hoped that now that the matter has been thoroughly threshed out the Government will step in and—while safeguarding its own interests and the sobriety of the workers—it will aid manufacturers by all means in its power by enabling them to use a class of alcohol which will be suitable to their special needs.

F. MOLLWO PERKIN.

THE GEOLOGY OF SOUTH AFRICA.[1]

TOWARDS the end of last century it appeared as if England had lost her well earned supremacy in geological research in Africa. In Germany, elaborate treatises dealing sometimes with her own African colonies exclusively, and sometimes with that of neighbouring British territory, monthly and almost weekly appeared. French geologists, too, produced essay after essay on their African colonies and possessions. Meanwhile, England was apparently content to lag behind.

It is fitting that the visit of the British Association to one of our most famous and most remote African colonies this year should witness the publication of two geological works, of the highest scientific standing, written by our own countrymen. Early this year, the comprehensive treatise by Mr. A. W. Rogers on the geology of Cape Colony made its appearance. Now, a few months later, we have presented to us the philosophic *résumé* of the geology of South Africa as a whole by Messrs. Hatch and Corstorphine.

Both volumes supply a long-felt want. In their method and conciseness both are equally British.

In a work treating with the richly metalliferous regions of the Transvaal it might have been expected that questions of economic interest would occupy many pages. It is an agreeable surprise to find that this is not the case. On the contrary, the geology of South Africa is here described in a thoroughly scientific manner, clearly and concisely worded. All essential details are brought within a compass of 312 pages of text.

In the opening chapter, on the history of research, ample recognition is given to A. G. Bain, the father of South African geology, and also to Stow. More recent workers cannot complain that their investigations have been neglected.

The book is divided into five parts. Part i. deals with the pre-Karroo rocks, in which those of southern Cape Colony are described in section i., and those of northern Cape Colony, the Transvaal, &c., in section ii. This separation into sections becomes necessary owing to the want of similarity in the succession of the pre-Cape rocks in the two regions.

The authors naturally give somewhat more space to the sequence in the Transvaal, more especially to a description of the upper division of the Witwatersrand system, which includes the famous "Banket." It is interesting to find that the stratigraphical position and age of this well known deposit remain unsolved, except that the authors consider the age to be vastly newer than the Archæan rocks and greatly older than the Table Mountain Sandstone.

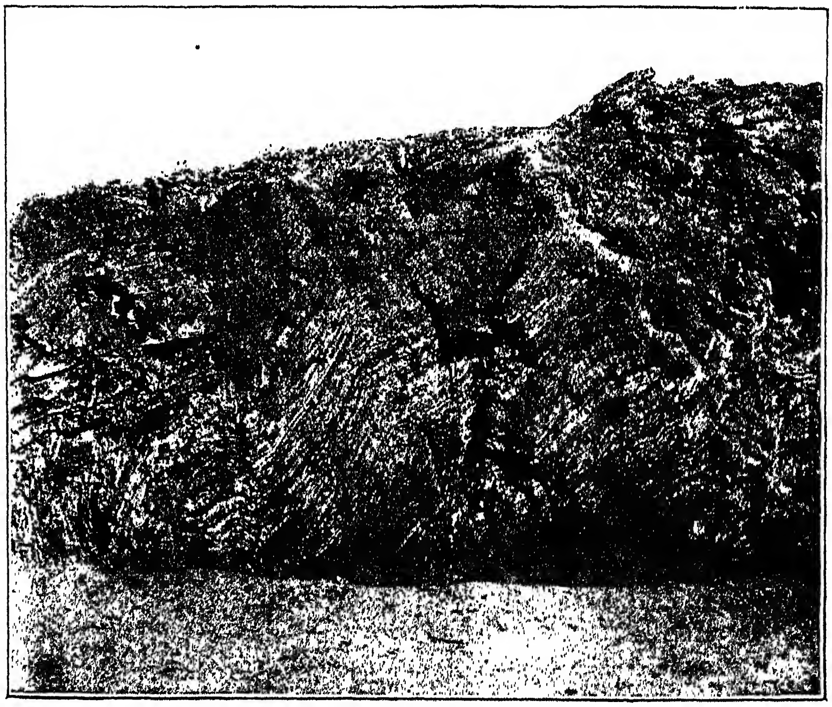

FIG. 1.—Contorted Band, Hospital Hill Slate, Show Yard, Johannesburg. From "The Geology of South Africa," by F. H. Hatch and G. S. Corstorphine.

The complicated nature of the stratigraphy of South Africa, other than that of the peninsula, will be gathered from the following tables:—

North of Cape Colony	Transvaal
Dwyka Conglomerate	Dwyka Conglomerate
Unconformity	*Unconformity*
Matsap Series	Waterberg Series
Unconformity	*Unconformity*
Griqua Town,	Pretoria Series
Campbell Rand and Keis Series	Dolomite and Black Reef Series
Unconformity	*Unconformity*
Volcanic Series	Ventersdorp Series
Unconformity	*Unconformity*
	Witwatersrand Series
	Unconformity
Namaqualand Series	Swaziland Series

This table opens up a vista of infinite possibilities.

The Karroo rocks are adequately dealt with in part ii., but in this and elsewhere Rhodesia,

[1] "The Geology of South Africa." By F. H. Hatch and G. S. Corstorphine. Pp. xiv+336. (London: Macmillan and Co., Ltd., 1905.) Price 21s. net.

Bechuanaland, and Natal receive scant notice. The coastal system, including the Uitenhage and Umtavuna Cretaceous rocks, profusely illustrated with typical fossils, occupies part iii.

The superficial deposits, somewhat summarily dismissed, form a separate chapter. Many of the interesting problems connected with them are not even hinted at. A classification by chemical composition is adopted.

The igneous and volcanic rocks, which take so large a share in South African stratigraphy, are described in connection with the systems with which they are more intimately associated.

Part iv. briefly discusses the igneous rocks of doubtful position. Too much space has here been allotted to the diamond-bearing deposits.

Part v. discusses the correlation of the South African strata. It contains much information guardedly expressed. This portion possesses the almost unique virtue of stating the arguments in favour of the correlation adopted by the authors. Few geologists will now dissent from the view that the Witwatersrand series is older than the Table Mountain Sandstone and newer than the complex of rocks termed Archæan.

Latter-day geologists will miss a chapter on structural and dynamical geology. The authors, and many will no doubt agree with them, have eschewed the problems entailing the use of modern physiographical and dynamical terminology. In dealing with rocks and fossils they have, however, occasionally been compelled to drop into technical language. Thus we met with *Cardium bullen-newtoni, Eriphyla rupert-jonesi* among fossils; while among minerals and rocks several of those mentioned wordily lengthen out what, to the general reader, would otherwise be a welcome page.

The authors have certainly succeeded in their self-imposed task "to correlate and systematise the valuable results of both official and private work." They are right in considering that what we know of South African geology lacks coherence. The best efforts, such as that of the authors, must for a long time be regarded as tentative and by no means final.

The volume is profusely and admirably illustrated with photographs of scenery and rock sections. Two coloured geological maps accompany the text, one of South Africa between Bechuanaland and the east coast and the Transvaal and the south coast, and one of the Transvaal. It is to be hoped that the half-mourning adopted for the Karroo system will not be perpetuated. Economically it is false; artistically it is ruinous.

W. G.

NOTES.

THE meeting of the French Association for the Advancement of Science was opened on August 3 at Cherbourg under the presidency of Prof. Giard.

WE regret to learn that Prof. L. Errera, professor of botany in the University of Brussels, and member of the Royal Academy of Belgium, died on August 1 at Uccle.

WE understand that the editorship of the "Fauna of British India," rendered vacant by the death of Dr. W. T. Blanford, has been offered by the Secretary of State for India to Lieut.-Colonel C. T. Bingham.

A REUTER telegram from Rio de Janeiro says that the Latin American Scientific Congress was opened on August 7, delegates from all the South American Republics being present.

THE sixth International Congress of Criminal Anthropology is to take place in Turin on April 26 next under the presidency of Signor Bianchi, Minister of Public Instruction.

PROF. RONALD ROSS and Prof. Boyce, of the Liverpool School of Tropical Medicine, will sail for New Orleans on Saturday to assist in dealing with the epidemic of yellow fever in that city.

WE regret to see the announcement that Mr. Alexander Bell, father of Dr. Alexander Graham Bell, and an active worker in educational science, especially in relation to the study of deaf-mutes, died at Washington on August 6.

MR. CHRISTOPHER HEATH, Emeritus professor of clinical surgery in University College, London, and a former president of the Royal College of Surgeons of England, died suddenly on Tuesday, August 8. Mr. Heath was the author of several standard works on surgical subjects.

THE Amherst College expedition for the observation of the eclipse of the sun on August 30 has departed for Tripoli, where the instruments will be mounted on the edge of the desert. The members of the expedition are Prof. David Todd, Mrs. and Miss Todd, and Mr. E. A. Thompson, and their attention will be chiefly devoted to the photography of the corona and of intra-Mercurial planet regions.

THE Treasury has renewed for a further period of five years the annual grant of 500*l*. to the British School at Athens. The promoters of the movement hope that an influentially signed petition for a similar grant to the British School at Rome may be also favourably considered.

PROF. GUIDO CORA informs us that the earthquake disturbances registered at the Pola Hydrographic Station on July 23 (see p. 298) were also recorded at the Osservatorio Ximeniano of Florence at 3.50 a.m. on the same date. Father Guido Alfani, from an examination of the seismograms, expressed the opinion that a severe and protracted earthquake must have taken place at an estimated distance of about 6800 kilometres (4225 miles).

WE notice with regret the death on July 26 of Prof. Bichat, dean of the faculty of sciences at the University of Nancy. Prof. Bichat was also director of the Electrotechnical Institute of Nancy, and took a very active part in all efforts for the improvement of secondary and higher education.

THE research fellowship in chemistry offered by the Worshipful Company of Salters, and tenable in the research laboratory of the Pharmaceutical Society, has this year been awarded to Miss Nora Renouf, who has been engaged in research work for the past two years in the society's laboratories. The Salters' fellowship is of the annual value of 100*l*., and was founded with the view of encouraging the application of the newest methods of scientific chemistry to the elucidation of pharmacological problems.

THE International Congress of Anatomy was opened in the morning of August 7 at Geneva. Three hundred representatives of the principal universities of Europe and America were present, including office-bearers of the five great anatomical associations of Great Britain, France, Germany, Italy, and the United States. One hundred and fifteen papers on various scientific subjects were put down for reading. The congress will conclude to-day with a banquet given by the city of Geneva to the delegates. The congress has accepted an invitation to assemble at Boston in 1907.

THE *Journal of the Royal Microscopical Society* for June contains two papers by Mr. J. E. Stead, F.R.S., one dealing with micro-metallography in general, and the other with the special processes for detecting phosphorised portions in iron and steel.

THE two articles in the July issue of the *Irish Naturalist* are devoted to local subjects, the Rev. Canon Norman completing his list of Irish ostracod crustaceans, while Mr. R. Ll. Præger discusses the distribution of fumitories in Ireland.

WE have to acknowledge the receipt of a complete copy, with the plates, of the first part of vol. lvii. of the *Proceedings of the Philadelphia Academy*. Many of the papers contained in this part have been already noticed in our columns, as they appeared in the monthly issues.

WE have received a fasciculus of "Illustrations of the Zoology of the *Investigator*," containing plates of crustaceans (part xi.) and fishes (part viii.). Special interest attaches to the plate of the crab *Lithodes agassizi* on account of the large size and peculiar form of this species, and also to the plates of deep-sea fishes, a few of which have only recently been described.

MR. J. E. ROBSON continues his catalogue of the Lepidoptera of Northumberland and Durham in vol. xv., part i., of the Natural Transactions of the aforesaid counties, dealing in this instance with the groups Pyralidina and Tortricina. Both these sections of the Microlepidoptera are but little studied by collectors, and the author confesses to considerable difficulty in dealing with the second of the two.

IN No. 1410 of the *Proceedings of the U.S. National Museum* Mr. E. Linton describes certain cysts of a cestode worm from a bottle-nosed porpoise, which are regarded as indicating a new species of Tænia. No. 1404 of the same publication contains the first part of a description, by Mr. C. B. Wilson, of the North American parasitic copepod crustaceans of the family Caligidæ. An account of the Argulidæ has already appeared in the same journal; the members of the present group are regarded by the author as of the greatest possible ecological interest, so that the study of their life-history cannot fail to yield important results.

ARTICLE 7 of vol. xx. of the Journal of the College of Science of Tokyo University contains an account by Dr. I. Ijima of the larva of an apparently new cestode worm which was recently found infesting a Japanese woman in extraordinarily large numbers. This larva has been provisionally described as a new generic and specific type under the name of *Pterocercoides prolifer*. It is believed to be a member of the Bothriocephalus group characterised by the absence of "bothria," a feature probably common to Ligula, with which the Japanese cestode may prove to be nearly related.

IN a paper published in the fourth volume of series iii. of the *Anales* of the National Museum of Buenos Aires, Dr. F. Ameghino records the presence of a perforation in the astragalus of the badger, the other living mammals in which this feature is known to occur being the dasyure, the giant armadillo, and the mole. The same volume contains a paper by Mr. F. Lahille on a new type of scombroid fish from Argentine waters, which has been named (in a preliminary notice published a couple of years ago) *Chenogaster holmbergi*. This fish, of which an excellent coloured plate accompanies the memoir, is a member of the same group as the New Zealand Lepidothynnus and Gasterochisma, which inhabit the same latitude as Chubat. From the New Zealand forms Chenogaster differs by the united dorsal fins, while it is distinguished from Gasterochisma by the small ventral fins and from Lepidothynnus by the presence of vomerine teeth. The three genera indicate a circumpolar Antarctic group.

ON a previous occasion a special notice was given in this Journal of Dr. Waite's account of the nesting habits of the fighting fish (*Betta pugnax*), as observed in an aquarium. In the *Records of the Australian Museum* (vol. vi., part i.) Dr. Waite publishes a preliminary note of these habits in the allied paradise, or rainbow, fish (*Polyacanthus opercularis*), of which specimens have likewise been successfully kept in captivity. After mentioning that at the commencement of the breeding season the male assumes a gorgeous nuptial coloration, the author goes on to say that the nest of this species is simpler and flatter than that of the fighting fish, a difference probably due to the habit of the former of nesting beneath shelter. The first eggs are often laid in a small mass of bubbles, others being added later; in consequence of this the eggs are raised quite out of the water, and thus hatched. It may be added that, according to older views of nomenclature, the name Polyacanthus renders void that of Polacanthus, applied many years later to a British dinosaur.

THE migrations and growth of plaice form the subject of a communication by Mr. A. Meek to vol. i., part ii., of the new series of the *Transactions of the Natural History Society of Northumberland and Durham*. After referring to previous experiments and observations, the author states that during last year 483 plaice (inclusive of a few other flat-fishes) were caught, marked, and returned to the sea on the Northumberland coast. Of these fish 52 were recovered; and among this number only 2 made conspicuous migrations, and only 7 may be said to have left the bays where they were liberated. Apparently, the small plaice on the Northumberland coast gradually travel from the sandy pools to the adjacent deeper water, where they spend the remainder of their immature condition. When four or five years old they migrate into the still deeper extra-territorial waters, and apparently show a constant tendency to reach increasing depths with advancing age.

A RESTORATION of one of the huge Miocene American perissodactyles of the family Titanotheriidæ is attempted by Prof. R. S. Lull in the July number of the *American Naturalist*, the species in question being a member of the genus or group Megacerops. The creature stands about 7 feet 4 inches at the withers, and measures rather more than 12 feet in length. The general proportions are those of a rhinoceros, although the limbs, probably to support the enormous weight of the body, are less angulated, and primitive features are displayed by the shortness of the back and in the structure of the fore-foot. Indeed, if we are to accept Prof. Lull's description of the latter, the definition of the group Perissodactyla requires modification, for the fore-foot of this titanothere is stated to be four-toed and symmetrical, with the main axis lying between the third and fourth digits after the artiodactyle fashion. As regards the nasal horns, which are branched at the summit, the author is inclined to believe, from the absence of groovings on the bone, that

the basal portion (which is all now remaining) was clothed with skin during life, and that upon this were growths comparable to the horns of modern rhinoceroses.

PROF. ALBERT M. REESE, of the Syracuse University, has gone to Florida, under the auspices of the Smithsonian Institution, says the *Scientific American*, to collect eggs of the alligator with which to work out its embryology; subsequently he will spend some time at the biological laboratory of the Carnegie Institution of the Dry Tortugas studying the material he collects. Twenty-five years ago alligators existed in great abundance in the region ranging from North Carolina to the Rio Grande of Texas, but as alligator leather became fashionable about that time the demand thus created has reduced the supply by at least 98 per cent. It is said that a person may travel now from Jacksonville to Miami, Fla., without seeing a single alligator. It is estimated that 2,500,000 alligators were killed in Florida from 1880 to 1894.

THE list of new garden plants for the year 1904 has been published as appendix iii. to the *Kew Bulletin*. This list not only affords information respecting new plants, but also gives official authentification to the names, thereby providing an accurate guide for horticulturists.

A REVISION of the genus Zexmenia, prepared by Mr. W. W. Jones, has been issued as No. 7 of vol. xli. of the *Proceedings of the American Academy of Arts and Sciences*. The genus is one of the helianthoid Compositæ restricted to tropical and subtropical America.

NATURE-STUDY, so far as it is founded on the four faculties of observation, deduction, memory, and constructive imagination, is closely allied to the methods of Sherlock Holmes; such is the gist of an article by Mr. Lamborn in the May number of the *Nature-study Review*, and teachers in search of a novelty in nature-study may be referred to the example which is quoted. A short article on observation bee-hives for the schoolroom, by Miss Comstock, suggests another line of work. There is also much truth in the reasons which Mr. L. A. Hatch assigns for failure in teaching the subject, the first and foremost being a want of the observational instinct.

THE *Indian Forester* for June contains many interesting articles relating to forestry and kindred subjects. A new species of Diospyros (*D. Kanjilali*) is described and figured by J. F. Duthie. An article on the prohibition of grass burning and its effects on the game of the country will be read with interest by both forester and sportsman. Another valuable illustrated article, entitled "Some Facts about Gutta Percha," by Mr. A. M. Burn Murdoch, contains a great amount of useful information, especially regarding the rubber trees of the Federated Malay States. The article gives a very clear idea concerning the species and their distribution, the measures adopted for their protection, together with harvesting, manufacture, and properties of the gutta percha. There are many other papers and reviews, together with matters of general interest, which will repay perusal by those interested in forestry and its sister subjects.

THE broad-minded view which the U.S. Department of Agriculture takes of its function for instituting inquiries is well exemplified in three bulletins which have been received from the Bureau of Plant Industry. In Bulletin No. 68 Mr. A. S. Hitchcock presents a carefully prepared classification of North American species of Agrostis. The author, in the preparation of this memoir, has consulted all the large herbaria in Europe; the number of species, including three new to science, is limited to twenty-seven, and these, together with the principal varieties, are fully described and illustrated. A method of exterminating Johnson grass by means of a root-digger is explained by Mr. W. J. Spillman in Bulletin No. 72, and the problem of range management in the State of Washington is discussed by Mr. J. S. Cotton in Bulletin No. 75. The latter pamphlet deals with the protection and seeding of land which had been over-grazed by nomadic stockmen. Experiments on land situated at an altitude of 5000 feet demonstrated that Timothy, brome-grasses, and tall fescue would be found suitable for sowing on these mountain pastures.

WE have received a copy of the year-book of the Norwegian Meteorological Institute for 1904, containing hourly observations of air pressure and temperature for Christiania, in addition to observations made three times daily, and monthly and yearly summaries at a number of other stations in Norway. There is also a valuable appendix showing the departures of the monthly and yearly values from the normal at a number of stations for each year from 1874 to 1904. Since 1903 the station at Bergen has undertaken the duties of weather prediction and storm warnings for the western part of Norway. This arrangement allows Prof. Mohn, director of the Norwegian Meteorological Institute, to devote more attention to general climatology, and is conducive to more rapid dissemination of forecasts of the depressions arriving from the Atlantic.

THE *Annuaire météorologique* of the Royal Observatory of Belgium for 1905, published under the superintendence of M. A. Lancaster, director of the Belgian Meteorological Service, contains a large amount of useful information relating to that country in particular and to meteorological science generally. For sixty-eight years the *Annuaire* referred to astronomy and meteorology combined, but since 1901 each of these sciences is separately dealt with. Some 240 pages of the work now in question contain valuable data relating to the variability of atmospheric pressure and rainfall for each month since 1833, and to the frequency of sunshine since 1886. The following contributions are worthy of special notice :—(1) A discussion of the late spring and early autumn frosts by Dr. Vanderlinden, containing valuable particulars as to the conditions under which they generally occur, and the possibility of foretelling their occurrence. (2) A bibliography of meteorological treatises by M. L. Vincent from the earliest times. The author gives most attention to general treatises, but anyone wishing to study special subjects, *e.g.* marine, agricultural, and medical meteorology, or weather prediction, will find it an invaluable guide. (3) A collection of meteorological and physical constants and conversion tables which will be found exceedingly useful for general reference.

CAPTAIN H. G. LYONS contributes to the *Geographical Journal* for August an instructive summary of the dimensions of the Nile and its basin. The length of the Nile is given usually as 5400 kilometres (3355 stat. miles) to the centre of Lake Victoria, or 6000 kilometres (3728 stat. miles) for the continuous water-way from the source of the Kagera to the sea; the area of its basin is given as about 2,900,000 square kilometres (1,119,737 square miles). It is now possible to measure the length of the river with sufficient accuracy to furnish a value which later surveys probably will not materially alter. The length of the Nile from Ripon Falls to Rosetta mouth is 5589 kilometres, or 3473 miles. The area of the catch

ment basin has been calculated from a map on the scale 1 : 4,000,000 for the Sudan and Uganda, and from one of 1 : 2,000,000 for Egypt. The area of catchment of the Nile basin is 2,867,600 square kilometres (1,107,227 square miles). The area of the basin will vary according to the distance to which its limits are considered to extend on the west of the Nile northwards of Khartum. Captain Lyons has taken it as far as the cliff of the desert plateau, or the first marked rise of the desert where the cliff is absent, probably, on the average, about 3 to 4 kilometres (2 to $2\frac{1}{2}$ miles) from the edge of the cultivation. The whole of the Nile basin below Khartum, and practically all the White Nile basin, are non-effective in increasing the river supply, since the occasional local cloud-bursts may be neglected. The Bahr el Ghazal, as has been shown by recent measurements of the volume discharged, is also practically non-effective.

MR. S. TETSU TAMURA has contributed to the *Monthly Weather Review* (February and April) two papers dealing with applications of the Fourier methods of analysis, one to ice formation and the other to the nocturnal cooling of the atmosphere.

A VERY compact form of direct-reading cymometer for the measurement of wave-lengths and frequencies in connection with electric-wave telegraphy is described by Prof. J. A. Fleming in vol. xix. of the *Proceedings of the Physical Society of London*. In the described form the cymometer can be used to measure not only the length of the outgoing wave from a sending aërial, but also the length of the wave being received. The instrument can further be used for measuring the capacity of a Leyden jar or the inductance of a circuit for high-frequency currents.

IN the *Journal de Physique* for May, M. Adrien Guébhard contributes a paper on photographic action, illustrated by curves showing the darkening due to development as a function of the time, and the superficial changes as a function of the sum of the causes producing them—as he calls it, the "photographic function." It is well known that the effect of greatly over-exposing a negative is to reverse the photographic action, sometimes producing a positive instead of negative impression. M. Guébhard discusses the theory that the photographic function, after reaching its maximum and descending to a minimum, attains a second maximum, followed by a second minimum, and he describes experiments in support of this view.

PROF. O. ZANOTTI BIANCO, of Turin, has published (Florence: L. S. Olschki, 1905) a short discussion on Dante's "Quaestio de Aqua et Terra" considered in the light of modern geodesy. The question as proposed by Dante was essentially whether the water of the terrestrial globe is anywhere higher than the land which emerges from it. This question resolves itself largely into what is the definition of height adopted. According to Dante's belief that the earth was a sphere, points would be at the same height if they were equally distant from the centre, and the fact that the earth is not spherical, but ellipsoidal, would thus afford, in effect, an answer to Dante's question according to which the sea-level is considerably higher at the equator than at the poles. This particular interpretation appears to be the one favoured by Prof. Bianco.

No. 29 of the monograph supplements of the *Psychological Review* contains the first part of a new series of "Yale Psychological Studies," edited by Prof. Charles H. Judd, a large part of which is devoted to a series of studies of eye movements in connection with optical illusions. The contributors are Messrs. C. H. Judd, Cloyd N. Macalister, W. M. Steele, E. H. Cameron, and Henry C. Courten. Some idea of the researches on eye movements may be obtained from the following necessarily fragmentary summary. In order to trace the movements of the eye during the fixation of different points in the visual field, a tiny speck of Chinese white was attached to the cornea, and kinematographs were taken showing its movements as the subject followed the various details of a diagram. This was applied in the case of several well known optical illusions in which the lines of figures appear distorted or equal lengths appear unequal. In another series of experiments the subject was made to record his impressions by a series of pin pricks.

IN the *Bulletin de l'Académie Royale de Belgique*, No. 5, p. 201, Prof. W. Spring describes experiments which he has made on the limit of visibility of fluorescence. A conical beam of light of great intensity was brought to a focus in solutions of fluorescein of gradually increasing dilution. Fluorescence was perceptible on an area equal to one square millimetre at the apex of the conical beam, when the solution contained 1×10^{-15} gram of fluorescein, but imperceptible when the solution was ten times more dilute. On the assumption that in the limiting fluorescent condition at least one molecule of fluorescein is present in each cubic centimetre of solution, the value 1×10^{-18} gram is calculated as the superior limit of the weight of a molecule of fluorescein, and $2 \cdot 5 \times 10^{-21}$ gram as that of the weight of an atom of hydrogen.

SOME interesting observations on the decomposition of silver oxide at high temperatures are recorded by Mr. G. N. Lewis in the current number of the *Zeitschrift für physikalische Chemie* (vol. lii. p. 310). The velocity of decomposition of the oxide, when heated at 330° C. to 350° C., is at first so small that no appreciable evolution of oxygen is observed during several hours. The rate of change increases rapidly, however, as decomposition proceeds, passes through a maximum, and then gradually falls to zero. Experiments carried out to elucidate the peculiar phenomenon indicate that the reaction is autocatalytic, the silver produced by the decomposition being the catalytic agent. Other substances, such as platinum black and manganese dioxide, are found to exert a similar influence on the rate of decomposition of silver oxide.

A CONTINUOUS series of articles on the radio-activity of the soil and of the atmosphere is being written for *Le Radium* by Prof. Geitel. These articles connect together the several original papers published by Prof. Geitel in conjunction with J. Elster, many of which have already received notice in these columns. The number of *Le Radium* for July 15 contains in addition an article on the results obtained by the use of radium in the treatment of cutaneous cancer. It is illustrated by some striking photographs.

IN a brief note in the current number of the *Atti dei Lincei* Prof. A. Righi states that, using an experimental method essentially different from that employed by Prof. McClelland, he has obtained results which fully confirm the connection maintained by the latter to exist between the atomic weight of a substance and the amount of secondary radiation which it emits when subjected to the β and γ rays of radium (compare NATURE, vol. lxxi., p. 543, and lxxii., p. 158). The method used was to measure the change of potential of a disc of the material suspended

in a vacuum when subjected to the radiation of radium. The disc being under two influences, namely, an increase in the negative charge owing to the impact of the β electrons and a loss of negative charge owing to the emission of a secondary radiation, the actual rate of accumulation of the negative potential measured inversely the rate of production of the secondary radiation.

THE Engineering Standards Committee has issued a report on the effect of temperature on insulating materials. A series of measurements showing the influence of temperatures ranging from 75° C. to 150° C. on the disruptive voltage, the resistance and the mechanical properties of the insulating materials used in industry, were made by Mr. E. H. Rayner at the National Physical Laboratory, by Messrs. Crompton and Co. at Chelmsford, and by Messrs. Siemens Bros. and Co. at Woolwich. The electrical properties of the materials do not seem to be greatly influenced by exposure at the temperatures given, but the material itself perishes on long-continued heating. An interesting point established is the extraordinary increase in resistance of the insulating substances which, owing to the removal of water, accompanies drying at 100° C. The price of the report is 5s. net.

AN interesting Parliamentary return just issued gives some particulars of the first three months' working of the Wireless Telegraph Act. Part of the return relates to licences, seventy-eight applications for which have been received; the majority of these are for experimental purposes, but a fair number are for commercial purposes. No less than four companies have applied for licences to establish stations to communicate with America; two of these have been granted, one is under consideration, and the fourth is offered with an alteration in locality. The paper also contains particulars of the working of the arrangement between the Post Office and the Marconi Co. It seems that 111 messages have been received by the Post Office for transmission to outward bound ships, of which 21 could not be delivered (in six cases at least through the senders' fault in transmitting after the latest guaranteed time). The number of messages received from ships at sea is 1655, which, if it does not represent a very great volume of business, still serves to show that the system is beginning to develop in practical utility.

A MOST interesting paper on a new carbon filament, read recently by Mr. Howell before the American Institute of Electrical Engineers, is published in the *Electrician* for July 28. The author claims to have produced a new allotropic modification of carbon, so different are the physical and mechanical properties of his filament, which is prepared in the following way:—An ordinary carbon filament made from a solution of cellulose is baked to as high a temperature as possible in an electric resistance furnace; it is then "flashed" in the usual manner, and afterwards again electrically baked. Although the first electrical baking considerably affects the final result, it seems that the graphite coating deposited during flashing undergoes a very marked change during the subsequent baking, which is especially remarkable considering the high temperature at which the deposit is formed. The filament possesses a very much lower specific resistance than ordinary filaments, and this is a disadvantage from the point of view of practical lamp making; but, on the other hand, the resistance-temperature curve rises instead of falls, which is a distinct gain, and will undoubtedly confer on the lamp an indifference to fluctuations of line voltage, and so enable it to be run at a high efficiency. The inventor claims a useful life of 500 hours at a power consumption of 2·5 watts per candle, which is an extremely good result for a carbon lamp.

THE De La More Press will publish in the autumn "A First German Course for Science Students," by Prof. H. G. Fiedler and Dr. F. E. Sandbach.

WE have received a copy of the first volume of the "Collected Researches" of the National Physical Laboratory. The volume contains five contributions, viz.:—An analysis of the results of the Kew magnetographs on "quiet" days during the eleven years 1890–1900, by Dr. Charles Chree, F.R.S.; the high-temperature standards of the National Physical Laboratory, by Dr. J. A. Harker; the construction of some mercury standards of resistance, with a determination of the temperature coefficient of resistance of mercury, by Mr. F. E. Smith; the range of solidification and the critical ranges of iron-carbon alloys, by Dr. H. C. H. Carpenter and Mr. B. F. E. Keeling; and the resistance of plane surfaces in a uniform current of air, by Dr. T. E. Stanton. All the papers have been published previously, three of them in the *Transactions of the Royal Society* and two in journals of other scientific bodies. As Lord Rayleigh says in a preface to the volume:—"A multitude of other problems of scientific and technical importance press for solution. Some of these are already in hand, but the rate at which progress can be made will depend in great measure upon the amount of support which may be forthcoming from those more immediately concerned in the development of industry. It is hoped that the publication of the present volume may serve as a stimulus, by showing the character of the work of which the Laboratory and the Staff are capable."

PROF. N. ZARUDNOI publishes in vol. xxxvi. of the Memoirs of the Russian Geographical Society the herpetological and ichthyological results of his journeys in eastern Persia. The Reptilia are represented by 72 species, the Amphibia by 6 species, and the fishes by 17 species, many of which, especially among the first division, are new species described by Prof. A. M. Nikolsky.

THE last volume of the Memoirs of the Russian Geographical Society, for ethnography (vol. xxv., 1), contains a very valuable bibliography, by M. Baltramaitis, of everything that has been printed about Lithuania (8514 titles), its geography, history, law, statistics, and ethnography, including folklore. This volume, which covers 614 pages, is followed by an appendix, which contains a list of Lithuanian and old Prussian books printed from the year 1553 to 1903 (2665 titles). The whole is admirably indexed.

NOTICE is given by the Clarendon Press of the first part of a new book on "Elementary Chemistry," by Mr. F. R. L. Wilson and Mr. G. W. Hedley. According to the preliminary announcement which has reached us, the ultimate object of the authors is "the cultivation of a scientific habit of mind in the pupils, through the medium of chemistry, rather than the mere acquisition of the facts of science."

MR. JOHN HEYWOOD has published a fourth edition of Mr. R. L. Taylor's "Student's Chemistry." The book has been enlarged and revised by Mr. J. H. Wolfenden, and an appendix on the radio-active elements and an introduction to the study of organic chemistry has been added. The volume contains more than six hundred

questions and problems, and is likely to continue to be a popular manual on the outlines of inorganic chemistry and chemical philosophy.

MESSRS. MACMILLAN AND CO., LTD., have issued a new and revised edition of stage vi. of Mr. Vincent T. Murché's "Object Lessons in Elementary Science," the price of which is 2*s*.

A FIFTH edition of Mr. W. W. Fisher's "Class Book of Elementary Chemistry" has been issued by the Clarendon Press, Oxford. The text has been entirely revised, and numerous additions have been made. Several chapters on organic chemistry, intended to serve as an introduction to this division of the subject, have been included in the new edition, which is now in line with the present state of knowledge of the subjects dealt with in the volume.

OUR ASTRONOMICAL COLUMN.

JUPITER'S SIXTH AND SEVENTH SATELLITES.—A telegram from Prof. Pickering to the Kiel Centralstelle announces that Dr. Albrecht has observed the recently discovered sixth satellite of Jupiter with the Crossley reflector of the Lick Observatory. The times of observation and the determined positions were as follows:—

G.M.T.		Position angle		Distance
		°		′
1905 July 25·95	...	55·0	...	25·1
" 26·97	...	52·7	...	24·3
" 27·93	...	50·7	...	23·6

(Circular No. 77, Kiel Centralstelle).

In Bulletin No. 82 of the Lick Observatory Dr. Frank E. Ross publishes the following set of elements for the orbit of Jupiter's seventh satellite, which he has computed from the observations made by Prof. Perrine on January 3, February 8, and March 6:—

Ecliptic Elements.

Mean Jovicentric Longitude at Epoch	...	333·55	1905 Jan. 0·0 G.M.T.
Longitude of Perijove	...	336·65	
" Node	...	237·23	
Inclination to Ecliptic	...	31·0	
" Jupiter's Orbit ...	...	32·0	
Longitude of Node on Jupiter's Orbit	...	238·6	
Elements referred to Earth's Equator.			
Mean Jovicentric Right Ascension...	...	328·18	
Right Ascension of Perijove ...	...	331·28	
" " Node	...	281·13	
Inclination to Equator	...	26·2	

Mean Daily Motion $=1°·358$
log $a=8·9004$
$a=52'·54$ (for log $\Delta=0·71624$)
$e=0·0246$
$P=265·0$ days
Distance at maximum elongation $=70'$.

Calculating from these elements the positions at the times of Prof. Perrine's observations, it was found that the residuals were satisfactorily small, but for five intermediate dates, on which observations were secured, they proved to be larger than were expected. Dr. Ross accepts this result as evidence of the large periodic perturbations, chiefly solar, to which the satellite is subjected. The above elements indicate that this satellite revolves about Jupiter in a *direct* orbit, for although a retrograde orbit was computed and found to fit the three primary observations, it did not agree with the positions obtained from the intermediate observations.

An ephemeris, covering the period July 1 to November 13, from which the following positions are taken, accompanies Dr. Ross's paper:—

		p.	*s.*				*p.*	*s.*
		°	′				°	′
Aug. 10	...	294	26		Sept. 9	...	292	53
" 20	...	293	36		" 19	...	291	58
" 30	...	293	45		" 29	...	290	59

On October 4 the distance will still be 59′, but after that date it will slowly decrease, until on November 13 it will be only 18′.

According to a note communicated by Prof. Perrine to the Astronomical Society of the Pacific, and reproduced in No. 4035 of the *Astronomische Nachrichten*, Dr. Ross has also computed the orbit of Jupiter's sixth satellite. This satellite, like the seventh, moves in a direct orbit, its period being 242 days. The eccentricity of the orbit is large, amounting to 0·16, and the inclination to the plane of Jupiter's equator is about 30°. The mean distance of the satellite from Jupiter is about seven million miles. Thus the periods, and therefore the distances from Jupiter, of the sixth and seventh satellites are nearly alike, their orbits mutually interlocking. Otherwise the two orbits are dissimilar.

THE FORMATION OF THE NEW NORTH POLAR CAP ON MARS.—According to Mr. Lowell's observations, as recorded in No. 22 of the *Lowell Observatory Bulletins*, the first frost of this year in the Arctic regions of Mars occurred on May 19. The region wherein the phenomena were observed had been under daily scrutiny since coming into view on May 11, but no new feature had been discovered. However, on May 19 an enormous, unmistakably white patch was seen which extended from the western edge of the old cap to a point on the terminator about one and a half times the old cap's diameter away, and reached down to latitude +63°. The deposit was so thin on its northern edge that the band girdling the old cap could be plainly seen showing through it, but on May 20 a bright nucleus formed on the southern edge of the frost-bound area.

The date of the first observation corresponds to August 20 in our calendar, and is 126 days after the summer solstice in the northern hemisphere of Mars. In 1903 the first frost effects were observed on Mars about 128 days after the summer solstice; thus the recent observation strongly confirms those made in 1903.

LIQUID AIR—PRODUCTION AND APPLICATIONS.[1]

IN the former of these papers the author details experiments showing the trustworthiness of a German silver platinum couple to measure temperatures in the neighbourhood of those of liquid air and liquid and solid hydrogen. The electric resistance of metals is an unsafe guide at very low temperatures, and the manipulation of gas thermometers involves much time and care. A thermo-electric junction would be much more convenient if trustworthy. That it is trustworthy the experiments go to show, but only within limits. If the constants of the formula for interpreting the observations be determined at temperatures between 90½° and 123½° abs., the formula will then give the temperature of solid hydrogen at low pressure as 15°·27 abs., whereas if the constants be deduced from experiments at a lower temperature, 20½° to 77½°, the interpretation formula then makes the temperature of solid hydrogen at low pressure 1¾° lower, *i.e.* 13°·5 abs., which the author considers more correct. Bearing in mind that at this very low temperature a difference of 1¾° is equivalent to a difference of 37° at the ordinary temperature, we see that the method has no confirmatory value, and can itself be trusted only over the range for which it has been verified by the careful use of gas thermometers. If, therefore, helium be procured in sufficient quantity for liquefaction or solidification, its lower temperatures, possibly within 5° of the absolute zero, will have to be ascertained by the low-pressure helium thermometer. For ranges of temperature over which its indications can be verified, the thermoelectric junction thermometer will have a useful sphere of work in saving the inconvenience of employing gas thermometers. Among important cautions given by the author is a warning that junctions made with soft solder are affected by the low temperature. The junctions should be made with hard silver solder, and the indications at the temperature

[1] "On the Thermo-electric Junction as a Means of Determining the Lowest Temperatures, and on Liquid Hydrogen and Air Calorimeters." Papers by Sir James Dewar, read before the Royal Society, June 8, 1905.

of liquid oxygen compared before and after exposure to the temperature of liquid hydrogen, to see whether there has been any change produced. A German silver platinum junction was employed, but as the result of his experience the author recommends German silver gold.

The paper on "Liquid Hydrogen and Air Calorimeters" gives an account of experiments in which the specific heats of substances are determined by measuring the quantity of liquid air or hydrogen which they vaporise in falling through a given range of temperatures. From these experiments it appears that, at temperatures between those of these two liquids, ice has only one-third of its specific heat at ordinary temperature, graphite has only one-tenth, while diamond has as little as one-nineteenth of its ordinary specific heat. The second part of this paper deals with the latent heats of the volatile liquids, that of hydrogen being given as 121 or 122 calories, of oxygen 51·15 calories, and of nitrogen 50·4 calories. The latent heat of liquid air is not yet definitely determined, but when there is a high percentage of oxygen it is about 54 calories. The specific heat of hydrogen is found to be substantially the same, whether the substance be liquid, occluded, or gaseous.

The employment, just mentioned, of liquid air to determine the specific heat of substances may be called a practical application, though, so far, its utility is limited to scientific research; and the present time, ten years after the introduction of the new and comparatively economical method of producing it, is suitable for a review of its applications generally, the further developments in the methods of producing it, and the extent to which it has been possible so far to realise the expectations founded on the appearance of the new method of production.

It will be remembered that down to the year 1895 the method of liquefying air developed and employed by Olszewski and Dewar was what is called the cascade method, in which a gas condensed at high pressure is vaporised at a much lower pressure, so as to produce a much lower temperature, one low enough, perhaps, to condense a more volatile gas highly compressed. Thus nitrous oxide was made to produce liquid ethylene at a temperature below −90° C., and the ethylene, boiled at low pressure, similarly produced liquid oxygen, nitrogen, or air at −140° C. These liquids, boiling in the open, reduced their residual portions to their well known boiling points, and, boiled at low pressure, produced much lower temperatures, but in no case low enough to act in the same way as a means of liquefying compressed hydrogen, which is so volatile that its critical temperature is below the lowest obtainable by boiling the atmospheric gases at low pressure. The nearest approach to the liquefaction of hydrogen was Olszewski's imitation of Cailletet's combination of the cascade system with sudden expansion. He obtained a similar result—the brief appearance of an evanescent mist, which just sufficed to show that hydrogen was, under proper conditions, liquefiable. An ingenious means for getting below the lowest temperatures obtainable on the cascade system by boiling oxygen or nitrogen at low pressure was adopted by Olszewski and Dewar, who mixed hydrogen, the former with oxygen, the latter with nitrogen, in the hope of making a substitute for a natural gas of intermediate properties, which, boiling at low pressure, would give a temperature low enough for the liquefaction of compressed hydrogen on the cascade system. Both attempts were unsuccessful, though Dewar thought that the nitrogen jelly behaved as if it had some condensed hydrogen in solution.

At this stage there appeared a new and more powerful method for cooling and liquefying gases, the self-intensive system, by which compressed gas, allowed to cool itself by expanding to low pressure at a free orifice, has its cooling accumulated by an interchanger, and so intensified continually. Thus oxygen, nitrogen, and air starting from ordinary temperatures, and hydrogen starting from a temperature below −200° C., can be made to cool themselves to the liquefaction point, and gradually liquefy themselves at ordinary pressure without the help of any less volatile liquid to assist the fall of temperature.

With such apparatus available, great expectations were indulged in as to the future possibilities of liquid air. As with electricity, the enthusiast and the impostor were soon at work, making unlimited promises to attract the interest of the public, and company schemes to attract their money. Liquid air as a source of power was going to eclipse and replace steam and electricity. As an artificial refrigerant it was to banish ice, ammonia, sulphur dioxide, and carbonic acid. In surgery it was soon to be the only anæsthetic, antiseptic, and caustic employed; in medicine it was to cure consumption and many other diseases. Our prominent scientific men cannot claim much credit for doing their duty to the public in this matter. In a few reported interviews some of them mildly recommended caution. In this country only one prominent worker with liquid air plainly warned the public at the beginning of this boom that such promises were either foolish or fraudulent, and declared that on the score of expense liquid air, as made by the new method, could never compete with steam as a source of power or with ice as a source of refrigeration. The last ten years have too fully justified the warning; but in the meantime large sums of money were extracted from the public in America by fraudulent liquid air companies, one of which attempted to continue operations in this country; and many business men in England held over orders for new refrigerating plants for some years, for fear lest, as soon as they had put one down, they might find it superseded by a liquid-air contrivance. Apart from scientific research, the nearest approach to a commercial application of liquid air began last autumn, when experiments were given at music-halls under the name of the "Magic Kettle." The performance was anything but a popularising of scientific knowledge, of which the performers themselves in most cases had none; besides which they purposely deepened the mystery of the matter by adding a little juggling, and making misleading statements.

Air liquefiers of the best make are now such perfect machines that they seem to offer no scope for improvement within the existing system. The chief attempt to improve the system consists in substituting an engine to do work for the free-expansion valve, in order to obtain more cooling for a given amount of compression. This device, in the form of a turbine, was discussed as early as 1895, but rejected on the ground of complication. In 1896 Lord Rayleigh suggested it in a letter to NATURE, and others have proposed or attempted it since. Thermodynamically it would be a great gain; but in apparatus of this kind a thermodynamic gain often actually involves a greater practical loss, owing to the importance of simplicity. In *Comptes rendus*, vol. cxxxiv. pp. 1568–1571, is an account of such an apparatus made by M. G. Claude, which is declared to have been entirely successful. As this is purely a question of economy and convenience, which are dominating factors commercially, the fact that this apparatus is not yet displacing others makes it likely that the complications involved are found to be a serious stumbling-block. They have hitherto prevented the adoption of a similar device in commercial refrigerating machines working with ammonia and carbonic acid, which are now made on such a very large scale that in them, if anywhere, the thermodynamic gain would outweigh the complications.

One of the most promising practical applications proposed for liquid air has been the manufacture of oxygen from air by liquefying it and letting the nitrogen boil away before the oxygen, separating them by distillation. Theoretically the power, that is, the cost, required should be small. The latent heat taken up by the two gases separately in volatilising should balance that given out by the air in condensing. One of the prominent names associated with attempts of this kind is that of Pictet, who was long believed to have liquefied oxygen and hydrogen at the time when Cailletet undoubtedly produced a mist of oxygen. In New York Pictet was associated with others in an attempt of this kind under a patent (U.S.A.) in which he commits the fallacy of expecting the gases to separate at a low temperature, but while both are still in the gaseous condition, the greater density of the oxygen taking it to the bottom of the container! The oxygen did not drop, but the scheme, the patent, the fallacy, and the investors' money did. Pictet next appeared with a French patent, in which the U.S. patent fallacy was replaced by another. He arranged to make

a gain of cooling by letting liquid air vaporise at a lower temperature than that at which it had condensed, taking up more latent heat at the lower temperature than it had given out at the higher; and he overlooked the fact that the difference would be balanced by the specific heat given out by the liquid while being cooled to the lower temperature! Under a fresh patent in England Pictet has now for some years been associated with powerful supporters in installing a large and costly plant at Manchester with the same object. None of the former fallacies appear in the new patent. Whether practical success will attend the effort remains to be seen.

The liquid oxygen, or air rich in oxygen, obtained by distillation from liquid air, if mixed with a good combustible, such as cotton wool, makes an explosive. The Austrian military authorities, and the engineers engaged in tunnelling under the Alps, both made long and careful trials of such explosives; but the inevitable arrangements were too cumbrous, and the results too uncertain.

The nearest attempt to make what is called a practical use of liquid air is that of Dr. Allan Macfadyen (see NATURE, June 18, 1903, p. 152, and October 22, 1903, p. 608). By freezing the bacilli of typhoid in liquid air he makes them brittle enough for trituration in a mortar. By centrifugalisation the intracellular poison can then be separated from more fibrous material, and then by the methods of Pasteur an anti-typhoid serum prepared which promises to be of real value.

The most pronounced successes of liquid air have been in connection with scientific research. It was with liquid air made by the self-intensive process with a Hampson machine that Sir William Ramsay discovered krypton, xenon, and neon, that Prof. Rutherford and Mr. Soddy proved the emanations of radium and thorium to be condensable and vaporisable, that Ramsay proved the evolution of helium from radium emanations, and many other important investigations were carried out. Finally, it was by an extension of the same process that hydrogen was liquefied.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION.

A NUMBER of valuable and instructive papers were contributed at the recent meeting of the British Medical Association at Leicester, but the majority were technical and of a medical nature. The following, in addition to those described last week (p. 330), are, however, of more general interest:—

In the section of medicine, Dr. Nathan Raw (Liverpool) read a paper on human and bovine tuberculosis, with special reference to bovine infection in children. He said that while agreeing with the German view that there were decided differences between the bovine and human tubercle bacilli, he believed that bovine tuberculosis was a danger to human beings.

Bovine tuberculosis affected young people, was traceable to infected milk, and infected the tonsils, the alimentary tract, the glands, and, through the blood, the meninges, the bones, the joints, and other parts, while human tuberculosis was air-borne, and infected adults by way of the lungs as pulmonary phthisis. In evidence of this Dr. Raw indicated the rarity of pulmonary phthisis in infants and children, and, on the other hand, the comparative rarity of other than pulmonary lesions in adults, and suggested, further, that early tuberculous disease, presumably bovine, appeared to be protective against phthisis, as the development of pulmonary tubercle was relatively rare in those of a strumous diathesis who had suffered in infancy from bone and gland lesions.

In conclusion, Dr. Raw alluded to the frequency of tuberculosis among cattle, and the importance of the inspection of cattle and dairies.

Dr. F. J. Poynton (London) gave the results of his experience of milk to which sodium citrate had been added in the feeding of infants. The addition of sodium citrate to milk results in the formation of calcium citrate, and milk so treated forms a much finer curd and is more digestible than untreated milk. The sodium citrate may be added to the amount of 1 to 2 grains to the fluid ounce of milk.

In the section of ophthalmology, Prof. Hess (Würzburg) demonstrated by a series of beautiful drawings the influence of light in causing a migration of pigment in the retina of cephalopods. He had found in these eyes visual purple which had hitherto not been detected in any invertebrate.

All cephalopods studied by him showed this pigmentary migration within the retina, but the rapidity of the migration differed in various species, and it was different in different parts of the same retina, especially in the small horizontal stripe which contained very long and small rods, and corresponded evidently to an area of maximum vision.

In the section of tropical medicine, Mr. R. Newstead, of the Liverpool School of Tropical Medicine, read a paper on ticks concerned in the dissemination of disease in man, and gave a description of the *Ornithodorus moubata* which conveys tick fever, a spirillar infection, in the Congo Free State.

Mr. Newstead had found that in many respects the habits of the *Ornithodorus moubata* were not unlike those of *Argas persicus*, but the inert character of the larva of *Ornithodorus moubata* was unique among the Ixodinæ, in that it passes the whole of its life within the egg. The female *Ornithodorus moubata* laid eggs which were hatched, not as larvæ, but as nymphæ, although on the ninth day the larva was fully formed and the egg shell split, but the young tick remained until the fifteenth day, when as a nymph it escaped simultaneously from its larva covering and egg shell.

Dr. Graham (Sierra Leone) contributed a paper on guinea worm and its hosts. He had found that the incidence of the disease corresponded with the incidence of a cyclops, the presumed intermediate host, both seasonally and as regards its maximum manifestation.

SOME ASPECTS OF MODERN WEATHER FORECASTING.[1]

AFTER referring to the circumstances in which he was called upon to deliver the evening discourse in the absence of the Dean of Westminster, the lecturer explained that he had chosen the subject, not because he regarded weather forecasting as the only, or, from the scientific point of view, the most important practical branch of meteorology, but because, in a general sense, the possibility of its application to forecasting—the deduction of effects from given causes—was the touchstone of scientific knowledge.

The process of modern forecasting was illustrated by the daily weather charts of the period from February 1, 1904, up to the evening of February 12, which exhibited the passage over the British Isles of a remarkable sequence of cyclonic depressions, reaching a climax in a very deep and stormy one on the evening of the lecture. It was thus pointed out that the barometric distribution and its changes were the key to the situation as regards the weather, and this was supported by exhibiting the sequence of weather accompanying recognised types of barometric changes, as shown in the self-recording instruments at the observatories in connection with the Meteorological Office.

Some cases of difficulty in the quantitative association of rainfall or temperature changes with barometric variations were then illustrated. The barometric distributions in the weather maps for April 8 and April 16, 1903, were shown to be almost identical, and yet the weather on the later date was 10° colder than on the earlier. The observatory records for June 22, 1900, showed that a barometric disturbance of about the fiftieth of an inch, too small to be noticed on the scale of the daily charts, passed across the country from Valencia to Kew, over Falmouth, in about twenty-four hours, and produced at each observatory characteristic changes of temperature and wind, and also in each case about a fifth of an inch of rainfall.

Some examples of the irregularity of motion of the centres of depressions were also given, including one which travelled up the western coasts of the British Isles on October 14 and 15, and down the eastern coasts on

[1] Abstract of a discourse delivered at the Royal Institution of Great Britain by Dr W. N. Shaw, F.R.S.

October 16 and 17, 1903, one which developed from scarcely visible indications into a gale on December 30, 1900, and one which disappeared, or "filled up," as it is technically called, on February 6, 1904. The conclusion was drawn that the suggested extension of the area of observation by means of wireless telegraphy from ships crossing the Atlantic would not immediately place forecasting in the position of an exact science, but would add greatly to the facilities for studying the life-history of depressions.

The irregularities and uncertainties illustrated by the examples given might be attributed in part to the complexities of pressure due to the irregular distribution of land and sea in the northern hemisphere. Charts of the mean isobars for the world for January and July showed greater simplicity of arrangement in the southern hemisphere, where the ocean was almost uninterrupted, than in the northern hemisphere, where there were alternately large areas of sea and land. The comparative simplicity of the south as compared with the north was also illustrated by a chart representing an attempt at a synoptic barometric chart for the world for September 21, 1901.

The simplification of the barometric distribution at successively higher layers of the atmosphere, as illustrated by Teisserenc de Bort's chart of mean isobars at the 4000-metre level, was pointed out, and illustrations were also given of the method of computing the barometric distribution at high levels from observations at the surface, using data obtained from observations at high-level observatories, or those made with balloons and kites.

Some indication of the connection between the complexity of the surface and the simplicity of the upper strata might be established by means of careful observations of the actual course of air upon the surface and the accompanying weather conditions.

The actual course of air along the surface was often misunderstood. The conventional S-shaped curves representing the stream lines from anticyclonic to cyclonic regions were shown to be quite incorrect as a representation of the actual paths of air along the surface. A diagram contributed to the *Quarterly Journal of the Royal Meteorological Society*[1] showed the computed paths for special case of a storm of circular isobars and uniform winds, travelling without change of type at a speed equal to that of its winds. An instrument made by the Cambridge Scientific Instrument Company to draw the actual paths of air for a number of different assumptions as to relative speed of wind and centre, and of incurvature of wind from isobars, was also shown, and the general character of the differences of path exhibited under different conditions was discussed.

In illustration of the application of these considerations to practical meteorology, it was noted that rainfall is an indication of the existence of rising air, and conversely the disappearance of cloud may be an indication of descending air. It was further noted that if the ascent and descent of air extended from or to the surface, the actual paths of air along the surface, as traced from the direction and speed of the winds, ought to show convergence in the case of rising air and divergence in the case of descending air.

The chart for April 16, 1903, was referred to for an obvious case of dilatation or divergence of air from a centre corresponding with fine weather, the centre of the area of divergence being specially marked "no rain," and the actual trajectories or paths of air for two different travelling storms were contrasted, to show how the rainfall might be related to the convergence of the paths of air. The two occasions selected were (1) the rapid travelling storm of March 24–25, 1902, and (2) the slow travelling storm of November 11–13, 1901.[2] The trajectories or actual paths of air for these two storms had been constructed from two-hourly maps drawn for the purpose from a collection of records of self-recording barographs, &c. Those for March 24–25 showed the paths to be looped curves with very little convergence, whereas those for the storm of November 11–13 showed very great convergence; so much so that if four puffs of smoke could be imagined starting at the same time from Aberdeen, Blacksod Point, Brest, and Yarmouth respectively, and travelling for twenty-four hours, they would find themselves at the end of the time enclosing a very small area in the neighbourhood of London.

Corresponding to this difference of convergence as shown by the paths was the difference of rainfall as illustrated by two maps showing the distribution of the rain deposited from the two storms. The first, with little convergence, gave hardly anywhere more than half an inch; the second, with its great convergence, gave four inches of rain in some parts of its area.

BREATHING, IN LIVING BEINGS.[1]

IT has been said that the most striking facts connected with respiration are its universality and its continuity. In popular language "the breath is the life." Breathing is not only a sign of life, it is a condition of its existence. Permanent cessation of breathing is regarded as a sign of death. Link up with this the icy coldness of death and you have two significant facts.

Respiration and calorification are therefore intimately related; in fact, calorification is one form of expression of the results of respiratory activity.

The popular view of respiration is an inference from what is observed in man and animals. During life the rise and fall of the chest goes on rhythmically from the beginning to the end. The respiratory exchanges effected in the breathing organs—lungs or gills—constitute "external respiration." This, however, scarcely touches the main problem, viz. what is called "internal respiration," or tissue respiration—*i.e.* the actual breathing by the living cells and tissues which make up a complex organism.

We are told that man does not live by bread alone. We know he requires, in addition, solids, fluids and air. Taking these to represent the three graces, then air is of all the graces best.

The higher animals have practically no reserve stores of air—unlike what happens with the storage of fats and proteids—and hence the necessity for mechanisms by which air is continually supplied to the living tissues, and also by which the waste product of combustion, viz. carbon dioxide, is got rid of. Closure of the wind-pipe, even for a few minutes, brings death with it from suffocation. The entrance of oxygen is prevented and the escape of carbon dioxide is arrested.

The process of breathing is common to all living beings—to plants and animals alike. It consists essentially in the consumption of oxygen by the tissues and the giving out of carbon dioxide. It is immaterial whether the animals or plants live in water or air, the principle is the same in both cases. Living active protoplasm demands a supply of oxygen.

All the world's a stage. The human body is at once a stage, and a tabernacle—a vast theatre—and the myriads of diverse cells of which it is composed, the players.

The cells or players, as active living entities, not only require food, but they require energy. The respiratory exchanges in and by the living cells provide the energy for the organism. This breathing by the cells is called "internal respiration." In a complex organism, therefore, the respiratory exchanges represent the algebraic sum of the respiratory activity of the several tissues that make up the organism. The various tissues, however, breathe at very unequal rates.

In one of his charming "contes philosophiques," Voltaire describes the visit of a giant of Sirius to our planet. Before reaching his journey's end he would have to traverse an aërial medium, and on arriving would see before him a fluid medium in continual movement, and tracts of solid land. After investigation—or no doubt he would be told, even though he was not personally conducted—that the water surface of this our globe is two

[1] Abstract of a discourse delivered at the Royal Institution of Great Britain by Dr. William Stirling.

and a half times greater than the land surface. He would discover that there are animals that live in air, others in water, and again others on land. Our visitor would find out that the respirable media are two—water and air—and that there are 210 parts of free oxygen in a litre of air, while there are only 3–10 dissolved in a litre of water.

Had Voltaire's friend paid us another visit during the present century, we should be able to tell him that the water of the Thames above London contains 7·40 c.c. of O per litre; at Woolwich only 0·25; the decrease being due to the pollution of the river. Putting it broadly, water contains only 3–10 parts per litre, while air contains 210. Water-breathers under good conditions have twenty times less O than air-breathers. It is as if air-breathers on land had the percentage of O_2 reduced to 1.

He would also be told that carbon dioxide—CO_2—is also remarkably soluble in water, and readily combines with certain bases present in water; thus water forms an admirable medium into which an animal may discharge its effete and poisonous irrespirable CO_2.

He would also be told that our blood contains 60 volumes per cent. of gases, and that there is more O and less CO_2 in arterial blood than in venous blood.

Perhaps the name of Sir H. Davy might be whispered to him, for he was one of the first to detect the presence of gases O and CO_2 in blood.

In story, one has heard of the "Quest of the Holy Grail." I have even listened with rapt attention to an entrancing lecture on the "Quest of the Ideal." For the cell, the quest is the "quest of oxygen," and it is not happy until it gets it.

We speak of a distinction between air-breathers and water-breathers. If, however, we push the matter to its ultimate issue, we find that all our tissues—and equally those of plants—live in a watery medium; in us the fluid lymph which exudes from our capillary blood-vessels, and in plants in the sap. Thus we come upon what at first seems a paradox, but is not so; all our cells not only live in water, but they live in running water. They are bathed everywhere by the lymph which is the real nutrient fluid for our cells. Thus, in its final form, all respiration is actually aquatic. The process of internal respiration, besides other conditions, requires the presence of a certain amount of water. In fact, all vital phenomena require the presence of water.

The unity and identity of the process in animal and vegetable cells, as the theatre of combustion, is the striking fact. The means by which the necessary oxygen is brought to the cells is as varied as the forms of animated organisms themselves. This function exists for the cells, and not the cells for the function.

If the mountain will not go to Mohammed, Mohammed must go to the mountain. There are, at least, two principles on which animal cells obtain oxygen.

The air or water containing air is carried to the cells. This is the principle adopted in the lower invertebrates, as in sponges and with regard to certain air-breathers such as insects.

The other principle is this, that an intermediary carries the respiratory oxygen from some more or less central localised or diffuse surface to the cells. This intermediary is the blood—an internal medium of exchange. The fluid part of the blood may carry the oxygen supply and remove the carbonic dioxide waste. This is the case in many of the invertebrates, and it reaches its highest development in the vertebrates. Hence in them the circulating and respiratory systems reach their fullest development.

In most invertebrates the fluid part of the blood contains the nutritive substances and also the oxygen and carbonic acid. In the vertebrates, the hæmoglobin of the red blood corpuscles carries the oxygen from the gills or lungs to the tissues, whilst the CO_2 is contained in and carried chiefly by the blood plasma from the tissues to the gills or lungs.

It is singular that in the cephalopods, such as the squid and cuttle-fish, the blood is bluish in tint; and this is due to the presence in the plasma of a respiratory pigment called hæmocyanin. This body has a composition like that of hæmoglobin, but copper is substituted for the iron of the hæmoglobin. Copper also exists in organic combination in the red part of the feathers of the plantain-eater or turaco.

The real aristocracy with genuine blue blood are the crab, lobsters, squids, and cuttle-fishes.

Perhaps one of the most striking ways of dissociating this accessory mechanism from the activity of the cell itself is by the use of a poison. When a person is poisoned by coal gas, what happens? The coal gas contains carbon monoxide. This gas does not poison invertebrate animals or plants. Still it kills vertebrate animals. Why? It does not kill by acting on the living cells, only by depriving them of oxygen and asphyxiating them. It combines with the respiratory pigment hæmoglobin. Chloroform, ether, and similar drugs destroy the actual life of the cell elements by destroying their irritability.

In 1771, Priestley found that air vitiated by combustion of a candle, or by the breathing of animals—such as mice—could be made pure or respirable again by the action of green plants.

Under certain conditions, however, Priestley found that plants gave off carbonic acid, and the air did not support combustion or animal life. He regarded these as "bad experiments," and he selected what he was pleased to regard as "good experiments," *i.e.* those in which the air, rendered impure by the respiration of animals, was rendered respirable by the action of green plants.

In 1779 John Ingen-Housz published his "Experiments on Vegetables, discovering their great power of purifying the common air in sunshine, and of injuring it in the shade and at night."

He confirmed Priestley's observations that green plants thrive in putrid air, and that vegetables could convert air fouled by burning of a candle, and restore it again to its former purity and fitness for supporting flame, and for the respiration of animals—or, as he puts it, "plants correct bad air."

In 1787 Ingen-Housz, an English physician at the Austrian court, found that only in daylight did green plants give off oxygen. In darkness, or where there was little light, they behaved like animals so far as exchange of gases is concerned, *i.e.* they used up oxygen and exhaled carbonic acid. He found also that all roots, when left out of the ground, yielded by day and by night foul air, *i.e.* carbonic acid.

In the same year, 1804—the year of Priestley's death—Nicolas Theodore de Saussure, a Swiss naturalist and chemist, published his "Recherches Chimiques sur la Végétation" (Paris, 1804), a veritable encyclopædia of experiments of the effects of air on flowers, fruits, plants, and vegetation generally, and on the effects of these on atmospheric acid.

It is an old adage—the exception proves the rule. The exception "probes" the rule as the surgeon's probe probes a wound. The tactus eruditus of the surgeon, by his probe—indeed an elongated tactile sense—enables him to discover the presence or absence of a body in a wound. Had Priestley used the probe of a bad experiment, he in all probability would have anticipated the discovery of Ingen-Housz.

Some of you, no doubt, recollect the words of Goldsmith's famous description of his own bedroom and of the furniture of the inn—

> "The house where nut-brown draughts inspired."

And how his imagination stooped to trace the story of—

> "The chest that contrived a double debt to pay,
> A bed by night, a chest of drawers by day."

As to himself he tells us how—

> "A night-cap decked his brows instead of bay,
> A cap by night—a stocking all the day."

Green plants contrive a double debt to pay; they give off oxygen by day, and at night exhale CO_2.

How do the vast number of plants, the microbes, the bacteria without chlorophyll get oxygen? Most of them get it as we get it. Some, however, cannot live in pure oxygen and are anærobic, such as the micro-organisms that cause tetanus, malignant œdema, and those that set up butyric acid fermentation.

Pushing the matter still further, it is extremely probable that the oxidation processes in our tissues are largely due to the presence of oxydases.

This raises the question as to the part played by the nucleus of a cell in its respiratory processes.

Is the source of muscular energy to be sought in oxidation or cleavage processes in tissues? In some animals there is not a direct relation between the muscular work and oxygen consumed, though there is to heat production. Bunge, on this ground, thought that the intestinal parasites of warm-blooded animals must have their oxygen at a minimum. In the intestinal contents there is no estimable oxygen; there active reduction processes go on. Entozoa might get oxygen from O_2 diffusing from blood-vessels.

Bunge found that intestinal worms of the cat and pike can live in an alkaline solution of common salt, free from gases, under Hg, for four to six days. They made active movements, and gave off much CO_2.

Ascaris lumbricoides from the intestine of the pig lived four to six days in 1 per cent. boiled NaCl solution. It made little difference whether oxygen or hydrogen was passed through the fluid. They lived seven to nine days if fluid was saturated with carbon dioxide, so that they have accommodated themselves to high percentages of carbon dioxide.

They give off to the fluid valerianic acid, an acid with a characteristic butyric acid odour. These worms contain a very large quantity of glycogen, the dry body yielding 20 per cent. to 34 per cent. of this carbohydrate.

100 grams Ascaris, placed in boiled normal saline solution, used per day—

0·7 gram glycogen,
0·1 „ sugar,
No fat;

and yielded—

0·4 gram CO_2
0·3 valerianic acid.

It would seem that glycogen had split into CO_2, and valerianic acid—

$$4C_6H_{12}O_6 = 9CO_2 + 3C_5H_{10}O_2 + 9H_2$$
$$720 = 396 + 306 + 18.$$

Is it a genuine fermentation?

Weinland found that he could express by Buchner's method a substance, "zymase," which could split glycogen into CO_2 and valerianic acid.

Turning now to respiration in invertebrate animals, and dealing first with those which live in water, let us see some of the contrivances by which this end is achieved. The mechanisms are but means to an end. The ultimate union of oxygen, and the discharge of carbon dioxide with the liberation of energy, occur in the protoplasm of the cell itself.

There are two distinct processes, and it may be that the oxygen is introduced by one portal and the carbon dioxide got rid of by another, or it may be that one portal may do for both processes—the letting in of oxygen and the giving off of carbon dioxide.

Although the principle itself is simple, the variety of mechanisms adopted by nature to secure this double function is remarkable. Let us glance at some of the mechanisms proceeding from the simple to the complex, and first with regard to those animals that live in water.

Consider the oceanic fauna. It is immense both from the point of view of number and variety. Save insects and certain groups of molluscs, all invertebrates are aquatic. Amongst vertebrates, fishes have aquatic respiration, and some mammals, *e.g.* cetaceans or whales, have water as their sphere of existence, though they depend on the air for their respiratory oxygen.

The evolution from an aquatic to an aërial mode of existence can be traced in the animal kingdom, and may even be seen within limits in the history of certain species.

Every living cell, animal or vegetable, requires for its continued existence a supply of oxygen, and every living cell exhales carbon dioxide. The exchange of these two gases between the fluids of the body and the outer medium is the process of respiration. The simplest form of respiratory exchange occurs where there is no specially differentiated organ or mechanism for this purpose, so-called diffuse respiration. The whole surface of the organism in a watery medium may be concerned in this respiratory exchange. This is only possible, however, so long as the boundary surface, skin, or otherwise is permeable to gases, and no great respiratory exchanges are necessary.

Before showing you some lantern slides, I should like to point out how one process is made to aid another.

Motion associated with respiratory processes.

Ciliary motion with respiration and the capture of prey for food.

The old idea of one function for an organ is exploded. One speaks of one man one vote. One man one value. It is not really so.

With Shelley we may say—

"Nothing in this world is single;
All things, by a law Divine,
In each other's being mingle."

As regards the surfaces for these respiratory exchanges for diffuse respiration, it may take place through the inner surface of the body cavity of cœlenterates, the under surface of the bell of a medusa, the tentacles of an echinus, the respiratory tree at the hind gut of the sea cucumber, or the intestine of the young of the dragon fly, or by the intestinal mucous membrane of the mites which have no lungs or other directly respiratory organ. In the higher animals we have tracheæ, gills and lungs.

In some animals, the respiratory mechanism is closely related to the motor apparatus, as in some crustacea. In some mollusca the nutritive and respiratory mechanisms are closely related. In the highest of all there is central apparatus—gills or lungs—for the respiratory exchange between the blood and the air, and a circulatory apparatus for carrying the blood to and from the respiratory organs. The adaptivity of insects to varied conditions of oxygen supply is marvellous.

Before showing some classical experiments and illustrating the principles already laid down, I should like again to direct your attention to the association of several processes with respiratory mechanisms.

[The lecture was illustrated by means of lantern slides, showing the respiratory mechanisms from the lowest to the highest animals, and also by a number of experiments dealing with the chemical exchanges in the process of respiration. Lastly, the classical experiment of John Hunter, on the pneumaticity of the bones of birds, was shown in the duck. A candle flame was extinguished when held in front of the divided trachea, when air was blown into the divided humerus bone of the wing.]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ON June 27, Amherst College, Massachusetts, conferred the degree of M.A. upon Mr. Lundin, of Messrs. Alvan Clark and Sons, the following being President Harris's characterisation:—"CARL AXEL ROPERT LUNDIN: Scientific expert in cutting and fashioning glasses of great telescopes. He has done important work on the large objectives of Russia, of the Lick and Yerkes observatories, and lately on the 18-inch objective of the Amherst College Observatory, which is wholly his work. In 1854 Amherst conferred the degree of Master of Arts on Alvan Clark, who had built our first telescope. The same degree, for a similar service, is conferred on his successor, who has kept pace with the progress of astronomical science."

AN interesting inquiry as to the representation of science in the principal public libraries of Paris is being made by the *Revue Scientifique*, and the results are published week by week, from July 1 onwards, in the form of letters and opinions from the principal librarians and professors of science in France. The opinion is generally expressed that an unsatisfactory state of affairs exists in libraries such, for instance, as the Bibliothèque nationale and the library of the University of Paris owing to the fact that the librarians are almost exclusively graduates in arts and letters, and ignorant of the requirements of men of science. It thus happens that, the available funds

being limited, preference is given in the purchase of foreign works to the departments of history, letters, and the arts, these being the subjects in which the librarians themselves have special interest and knowledge. Important scientific books are thus often overlooked. The current books of reference and the principal foreign journals are difficult of access, and are not at hand for immediate use; journals are often not available for a year, or more, after the date of issue owing to their being sent to the binders. For these reasons, and on account of the time wasted in waiting and formalities, the principal libraries are hardly used at all for scientific purposes by most of the workers engaged in active research. The professors and teachers of Paris consider that the special libraries attached to the actual laboratories are more valued and are of greater use than the larger and more general libraries, and that these should be coordinated so as to be available for any properly accredited worker. On the other hand, there seems to be a desire on the part of the Government to limit the usefulness of these actual working libraries by reducing the grants formerly allotted to them. Some of the criticisms of the Paris libraries and suggestions for their amelioration are not without application in this country.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 15.—"Contributions to the Physiology of Mammalian Reproduction. Part i., The Œstrous Cycle in the Dog. Part ii., The Ovary as an Organ of Internal Secretion." By F. H. A. **Marshall** and W. A. **Jolly.** Communicated by Prof. E. A. Schäfer, F.R.S.

The experiments lead to the conclusion that the ovary is an organ providing an internal secretion which is elaborated by the follicular epithelial cells or by the interstitial cells of the stroma. This secretion circulating in the blood induces menstruation and heat. After ovulation, which takes place during œstrus, the corpus luteum is formed, and this organ provides a further secretion the function of which is essential for the changes taking place during the attachment and development of the embryo in the first stages of pregnancy.

June 8.—"Researches on Explosives." Part iii. By Sir Andrew **Noble,** Bart., K.C.B., F.R.S.

The principal object of the researches which are communicated in this paper was to ascertain, with as much accuracy as possible, the differences in the transformations which modern explosives suffer when fired under gradually increasing pressures. The first part of the paper gives a description of the varied apparatus employed.

Although the author has made experiments with many other explosives, those examined in this paper are three in number:—(1) Cordite; (2) the cordite known as M.D.; and (3) a tubular nitro-cellulose.

The modes of observation and calculation followed are described, and then in tabular form are given the results of the series of experiments on the three explosives named. These tables being too extensive to reproduce in full, the results of the experiments at the lowest and highest densities alone are given:—

	Cordite Mark I.		M.D. Cordite		Nitro-Cellulose

Comparative potential energy.	0·9825	1·0000	0·8401	0·8842	0·7389	0·7686

If the figures given in these tables be carefully examined, it will be observed that for the three explosives the transformation on firing appears, in all, to follow the same general laws.

Thus in all three there is, with increase of pressure, at first a slight increase, afterwards a steady decrease, in the volume of permanent gases produced.

In all three explosives there is, with increased pressure, a large increase in the volume of carbonic anhydride, and a large decrease in the volume of carbonic monoxide. In the volume of hydrogen this decrease with increase of pressure is very great; while methane, the percentage of which with low pressures is quite insignificant, very rapidly increases, and at the highest density is from twenty to thirty times greater than at the lowest density.

There are some variations in the percentages of nitrogen and water vapour, but on the whole these constituents may be considered to be nearly constant.

The units of heat developed show with increased pressure a slight decline at first, but afterwards increase somewhat rapidly at the higher pressures.

In the tables submitted it will be observed that the specific heats and the temperatures of explosion have been given, but with respect to temperatures so far above those in regard to which accurate observations have been made the figures given can only be taken as provisional.

These temperatures have been obtained by dividing the units of heat (water gaseous) by the specific heats; although provisional, they can safely be used in comparing the temperatures of explosion of the three explosives.

The comparative approximate potential energies are obtained by multiplying the volume of gas produced by the temperature of explosion. The means for the three explosives are respectively:—cordite, 0·9702; M.D., 0·8387; nitro-cellulose, 0·7464. The highest potential energy (taken as unity), it will be noted, was obtained from cordite at a density of 0·5.

It is submitted that the wide differences in the transformation of the three explosives with which the experiments have been made justify the general conclusion at which Sir F. Abel and the writer arrived in the year 1874 (*Transactions of the Royal Society*, vol. clxiii. p. 85) with respect to gunpowder, viz. that any attempt to define by a chemical equation the nature of the metamorphosis which

an explosive may be considered to undergo would only be calculated to convey an erroneous impression regarding the *definite nature* of the chemical results and *their uniformity* under different conditions.

The paper continues with a description of the experiments made to determine the time required for the complete ignition of certain explosives, and also of other experiments to determine the rate at which the exploded gases part with their heat to the walls of the vessels in which they are confined; and in conclusion it is pointed out that the experiments made on erosion, with the three explosives referred to in this paper, and with some other explosives, have satisfied the author that the amount of absolute erosion is governed practically entirely by the heat developed by the explosion.

"Colours in Metal Glasses, in Metallic Films, and in Metallic Solutions." II. By J. C. Maxwell **Garnett.**

Expressions, giving the refractive index and the absorption coefficient (the optical constants) of a compound medium consisting of metal (1) in small spheres (granular), and (2) in discrete molecules (amorphous), diffused through an isotropic non-dispersive transparent medium (the solvent), in terms of the corresponding optical constants of the normal metal, were first obtained. The particular formulæ, which apply when the volume proportion (μ) of metal in the compound medium is small, followed immediately. By means of these formulæ and of the numerical values of the optical constants of gold, silver, and copper for monochromatic light of several different wavelengths, the values of the corresponding optical constants of diffusions of spheres and of molecules of these metals, in glass, in water, and *in vacuo*, were calculated and tabulated. The absorptions of monochromatic light by specimens of gold and copper ruby glass and of silver-stained glass were measured. A comparison of the measured absorptions of gold ruby glass with the calculated absorptions of gold spheres and of gold molecules diffused in glass, and a collation of the results with others previously published,[1] show that the colour of gold ruby glass is primarily due to the presence of spheres (not molecules) of the metal. The presence of crystallites, formed by the coagulation of the gold spheres, and reflecting red light, accounts for the irregular blue and purple colours sometimes transmitted by gold glass. Further, when the absorptions of a colloidal solution of gold in water are compared with the calculated absorptions of gold spheres and molecules diffused in water, it appears that colloidal gold consists of small spheres in suspension.

The close similarity between the observed absorptions of glass stained (amber) with silver, and the calculated absorptions of silver spheres in glass—those of a diffusion of silver molecules in glass are quite different—indicates that the stained region must contain small spheres of silver. The presence of silver spheres (but not of discrete molecules of silver) also accounts for the brilliant blue reflection from the interface between the stained and unstained regions of Stokes's specimens of silver glass. Ehrenhaft's[2] description of the nature and position of the absorption band observed in the spectrum of colloidal solutions of silver describes so well the position of the absorption band determined by calculation for a diffusion of silver spheres (but not of silver molecules) in water as to justify the conclusion that the bulk of the silver present in colloidal solution is in the form of small spheres, little, if any, being in true solution (*i.e.* molecularly subdivided); and this conclusion is confirmed by the fact that the refractive index of a colloidal solution of silver, which was measured by Barus and Schneider, is precisely that which calculation gives as the refractive index of a diffusion of silver spheres (but not of molecules) in water.

A comparison of the observed and calculated absorptions shows that copper ruby glass owes its colour to the presence in the glass of small spheres of metallic copper; but some copper molecules are probably also present.

Calculation proves that diffused spheres of cobalt would give a reddish colour to glass. Cobalt glass is not coloured by the metal in the metallic form.

1 *Phil. Trans.*, A, 1904, pp. 385 *et seq.*; NATURE, vol. lxx. p. 213 (June 30, 1904).

2 Felix Ehrenhaft, *Ann. der Phys.*, vol. xi. p. 489 (1903).

The colours produced in gold, silver, and soda glasses by the radiation from the emanation from radium suggest that these glasses contain free ions of the metal, and that it is by the discharge of these ions and the consequent reduction of the metal that kathode and Becquerel rays are able to colour the glasses.

Curves were constructed to show how the calculated absorptions and reflections of red, yellow, green, and blue light by gold and silver films vary with the volume proportion, μ, of metal in the film; and a comparison of these calculated colour changes with those exhibited by the gold and silver films, which Faraday and Beilby had prepared, when subjected to heat and to pressure, indicated that (*a*) the films as first prepared were in the amorphous or granular phase; (*b*) heating diminished the density of the film, while pressure was able to increase that density again; and finally (*c*) this diminution of density was probably effected by the passage of the metal from the amorphous to the granular phase, and by the growth of the larger granules at the expense of the smaller, while increase of density was accomplished by changing some of the metal from the granular to the amorphous phase.

Optical and other evidence led to the conclusion that Carey Lea's silver was not allotropic, but consisted of normal silver in a finely divided (but not necessarily granular) state. It appeared, therefore, probable that many forms of metals, which have hitherto been supposed to be allotropic because they possessed optical properties distinct from those belonging to the metals in their normal states, were merely cases of fine division. Thus the properties of Bolley's lead, of Schützenberger's silver, and of other alleged cases of allotropy cited by Roberts-Austen ("Metallurgy," p. 90), do not require the postulation of an allotropic molecule for their explanation.

Faraday Society, July 3.—Mr. W. R. Cooper in the chair.—Some notes on the rapid electro-deposition of copper: Sherard **Cowper-Coles.** The various processes for increasing the current densities in copper deposition by using mechanical means for keeping the copper smooth are classified as follows:—(1) revolving or moving the kathode; (2) burnishing the copper during electrodeposition; (3) insulating the growths on the copper so as to prevent further increase; (4) rapid circulation of the electrolyte; (5) revolving mandrel at a critical speed (centrifugal process).—The use of balanced electrodes: W. W. Haldane **Gee.**—The electrolytic oxidation of hydrocarbons of the benzene series, part ii., ethyl benzene, cumene and cymene: H. D. **Law** and Dr. F. Mollwo **Perkin.**—The electrolytic analysis of antimony: H. D. **Law** and Dr. F. Mollwo **Perkin.**—Notes on heat insulation, particularly with regard to materials used in furnace construction: R. S. **Hutton** and J. R. **Beard.**—Storage batteries and their electrolytes: R. W. **Vicarey.**—Alternate current electrolysis: Prof. E. **Wilson.**—The two last papers were taken as read, and the discussions postponed until the autumn.

DUBLIN.

Royal Irish Academy, June 26.—Prof. R. Atkinson, president, in the chair.—Prof. Ronald **Ross** gave an account of the researches which resolved the malaria problem, and took occasion to refer to the interesting mathematical problems connected with the diffusion of mosquitoes.

PARIS.

Academy of Sciences, July 31.—M. H. Poincaré in the chair.—The study of refraction at all heights. Formulæ relating to the determination of the coordinates of the stars: M. **Lœwy.** A development of a system of formulæ allowing of the deduction of the positions of two pairs of stars according to the new method given in the *Comptes rendus* for July 17. Three tables of solutions accompany the paper.—On an endoglobular hæmatozoa found in the jerboa: M. **Laveran.** The parasite is described and classified as *Haemogregarina Balfouri.*—On a secondary reaction of the halogen organo-magnesium compounds: Paul **Sabatier** and A. **Mailhe.** The cause of the low yield sometimes observed in the reaction between a ketone

and an alkyl magnesium halogen compound is due to a secondary reaction resulting in the formation of a substituted ethylene. This tendency to the formation of an unsaturated hydrocarbon is especially marked in the case of the isobutyl derivatives. Details are given of several cases.—On the theory of surfaces and of envelopes of spheres in anallagmatic geometry: A. **Demoulin.**—On the properties of a holomorphic function in a circle where it does not take the values zero and unity: Pierre **Boutroux.** —On a new series of polynomials: A. **Buhl.**—On sliding friction: M. **de Sparre.** A solution of a problem enunciated by M. Appell in his treatise on mechanics. —The passage of electricity through gaseous layers of great thickness: E. **Bouty.** It has been shown in previous papers that the critical field $y=a\sqrt{p(p+b)}$, where p is the pressure (above 0·1 mm. of mercury), a the dielectric cohesion of the gas, and b a constant for the given flask and gas. In the present communication the constant b is found to be in inverse proportion with the thickness of the gaseous layer, e. The formula thus becomes

$$v=a\sqrt{p\left(p+\frac{k}{e}\right)},$$

where k is a constant which depends only on the nature of the gas.—The electrolytic detector with a metallic point: G. **Ferrié.** An experimental study of the use of the imperfect contact of a fine metallic point and an electrolyte as a detector for Hertzian oscillations.—On the phenomenon of Marjorana: A. **Cotton** and H. **Mouton.** A study of the behaviour of solutions of colloidal iron hydroxide in a strong magnetic field.—On a megaphone: G. **Laudet** and L. **Gaumont.** A gas flame, mechanically controlled, is used to intensify the sound waves.—On the state of matter in the neighbourhood of the critical point: Gabriel **Bertrand** and Jean **Lecarme.** Experiments made upon solutions of potassium bichromate in water and of alizarin in alcohol, at temperatures slightly above the critical points, have led to the conclusions that slightly above and below the critical temperature both the liquid and gaseous states exist simultaneously.—On the different states of oxidation of aluminium powder: M. **Kohn-Abrest.** Aluminium powder was heated by electrical means to various temperatures in a current of air; evidence was obtained of the formation of an oxide AlO.—The influence of the fragility of steel on the effects of mechanical treatment in a boiler works: Ch. **Frémont.**—The modification produced in the metal of rivets produced by the operation of riveting: M. **Charpy.**—On the constitution of sparteine: Charles **Moureu** and Amand **Valeur.** The authors summarise their recent work on this alkaloid, and propose a formula for it which is completely in accord with the facts known up to the present.—Chemical oxydases: G. **Baudran.**—On the variations of the basic function in chromium salts: Albert **Colson.**—On the presence of bile pigments in the medicinal leach: Camille **Spiess.**—Folded faults and horizontal overlapping in the Mesozoic of Portugal: P. **Choffat.**—On the geology of the southern Carpathians: G. M. **Murgoci.**—Observations on the mode of formation of deposits of blende enclosed in the stratified rocks: A. **Lodin.**

CALCUTTA.

Asiatic Society of Bengal, June 7.—Religion and customs of the Uraons or Oraons: Father **Dehon,** S.J., communicated by E. A. Gait. An account of the reputed origin, mythology, ceremonies, and folklore of an agricultural tribe now settled in Chota Nagpur, but thought to have come from farther south.—Note on a decomposition product of a peculiar variety of Bundelkhand Gneiss: C. **Silberrad.** A white clayey material found in the Ajaigarh State has been submitted by the author to Dr. O. T. Silberrad, the analysis of which is compared with that of pinite. The two substances were found to resemble one another.

July 5.—Four new barnacles from the neighbourhood of Java, with records of Indian pedunculate forms: Dr. N. **Annandale.** Of the new species, two belong to the genus Scalpellum, two to Alepas. Of the former, one is remarkable for its great size and for the reduction of the calcified valves; the other for its habit of forming a regular, branched, though not organically connected, colony of several generations. One Alepas is larger than any hitherto described. The specimens were presented to the Indian Museum by the Eastern Telegraph Company, and come, with one exception, from a depth of 160 fathoms. A list of the pedunculate cirripedes known from the seas of British India is added.—Additions to the collection of Oriental snakes in the Indian Museum, part ii.: Dr. N. **Annandale.** Notes on specimens lately received from the Andamans and Nicobars, with the description of a new sea-snake and a list of the Ophidia known to occur in these islands.—The Tibetan version of the Pramana-samuccaya, the first Indian work on logic proper, recovered from Tibet by the late Tibet Mission: Prof. Satis Chandra **Vidyābhūsana.**—Materials for a flora of the Malayan Peninsula, No. 17: Sir George **King,** F.R.S., and J. S. **Gamble,** F.R.S. This contribution commences with natural order Myrsineæ, and is continued by Sapotaceæ, Ebenaceæ, Styraceæ, and Oleaceæ. The draft of Ebenaceæ was prepared by Sir George King, that of the other orders by Mr. J. S. Gamble; but the new species are given under their joint names.

THURSDAY, AUGUST 17, 1905.

THE MATHEMATICS OF NAVAL STRATEGY AND TACTICS.

Manuel Pratique de Cinematique navale et maritime. By Captain Leon Vidal. Pp. viii+171. (Paris: Gauthier-Villars, 1905.) Price 7.50 francs.

THIS book was undertaken by the author in accordance with instructions from the Minister of Marine issued seven years ago. Captain Vidal was directed to collect in a single volume the numerous essays on mathematical naval tactics contributed by various authors, French and foreign, and scattered over many publications. Officers of the French Navy were asked officially to give all possible assistance to the compiler, and many of them have done so. The laborious task has been admirably performed, various problems dealt with have been classified, and those relating to similar subjects have been grouped in distinct chapters. Captain Vidal has drawn largely upon work done by other officers, and acknowledges the fact. He is an enthusiast on the subject and has supplemented theorems due to others by much original work, extending or completing his scheme. Solutions alone are given and detailed demonstrations are avoided, so that the volume is compressed within narrow limits in proportion to the range and variety of subjects dealt with. In order to facilitate the practical use of his book by naval officers, elaborate numerical tables have been calculated by which readers can construct diagrams representing particular cases that may require to be dealt with either during naval manœuvres or in warlike operations. Numerous illustrations are introduced, and the descriptions are brief and clear throughout. Captain Vidal had to examine and collate an enormous mass of material produced during the last thirty years, and it is not surprising, therefore, that he has been so long engaged on the book. French naval officers and professors have done most in this field, but foreign authorities have also been laid under contribution, and the volume will probably long remain the chief book of reference on its special subject.

The science of naval cinematics, says the author, "consists in the study of the movements of vessels considered ordinarily as moving points, but in many instances it also takes account of their length and gyration, as well as their powers." For the most part, in the strategical theorems dealt with it has been assumed that ships may be treated as particles, the influence of length and turning-power being neglected. Further, it is generally assumed that movements take place in a calm and tideless sea. Certain corrections are suggested subsequently in order to make allowance for wind, wave, and current, but these sections are very brief, besides being incomplete in treatment, as is indeed unavoidable from the nature of the case. The turning-powers of steamships are but lightly touched, although they are most important in tactical manœuvres either for single ships or squadrons.

It is well known that the mathematical training of French naval officers is more extensive than that given to officers in the Royal Navy, and Captain Vidal is exceptionally well equipped in this respect, even among French officers. The book is indeed mainly a collection of geometrical theorems, in two dimensions, bearing upon the movements of ships or squadrons performed under certain assumed conditions. Many of these theorems can have little practical value, but not a few have been made the basis of modern French naval manœuvres. The fundamental idea is that when the course of a ship departs from a straight line it may be assumed to follow a logarithmic spiral. Captain Vidal enumerates the principal properties of that curve, and gives tables for estimating the lengths of arcs and chords, the values of tangents at different points, and other useful items. He takes special cases for spirals described about a fixed point, or about a point in the rectilineal course of another moving body, so as to examine the relative positions, from instant to instant, of two vessels or two squadrons. Theorems attaching to the well-known "curves of search" employed by ships when scouting, or endeavouring to detect the position of an enemy who attempts either to arrive at or depart from some fixed point, are discussed at length. In another chapter theorems dealing with the movements of two vessels such as may take place in single-ship actions are grouped and discussed fully. In a third chapter the most effective methods of concentration for scattered ships belonging to a fleet sent out for purposes of observation and scouting are dealt with. In another section the "lines of observation" to be patrolled by ships of a fleet, and the organisation required in order that an enemy cannot pass through the line without detection, are discussed. The influences of currents in rivers on the movements of vessels and the effect of wind and sea are also briefly investigated.

Captain Vidal writes fully as much as a mathematician as a naval officer. In his opinion the study of mathematics is both necessary and beneficial to all naval officers, whose duty he considers it to be to lay down conditions for programmes of ship-construction. Consequently he urges that officers should understand the work of the engineer and the trend of industrial progress if they are to give good advice and be the *corps directeur* of a modern fleet. Naval officers must, in his opinion, "make, in war, the synthesis of actual forces and guide them in producing the desired effects." To ensure success in this high mission the study of naval cinematics is essential, in Captain Vidal's judgment, since every advance in that science "enables one to foresee more clearly the results of movements of ships and to employ new combinations with intelligence." There is much force in this contention, but the class of work dealt with by Captain Vidal could be undertaken only by the *élite* of officers in the Royal Navy. His treatment would be over the heads of average naval men, and it is not likely to assist them in their daily work. The fact that the standard of mathematical attainment by average officers in our naval service is not so high

as in the French Navy may reduce the number of English readers of the book. But, happily, we possess many naval officers fully competent to take their place in scientific discussions of naval strategy and tactics. They will find much that is suggestive in Captain Vidal's book, and may be trusted to appreciate its investigations properly as well as to deduce therefrom rules for guidance, which will assist brother officers not so well instructed as themselves in the practical application of the theorems which Captain Vidal has collected. Shortly stated, the volume is better suited for the student than for the average naval officer, but it deserves a place in the professional libraries of all modern fleets.

W. H. WHITE.

THE CORRESPONDENCE OF HUYGENS.

Œuvres complètes de Christiaan Huygens. Publiées par la Société Hollandaise des Sciences. Tome dixième. Correspondance 1691–1695. Pp. 816. (Nijhoff: La Haye, 1905.)

THIS volume completes the publication of the scientific and miscellaneous letters of Huygens, the ten volumes comprising in all twenty-nine hundred letters and memoranda. There is, perhaps, not so much variety in the contents of the present volume as in those of previous ones, and the great majority of the letters of interest written during the last five years of Huygens's life have been published before, but they have now in many cases been further illustrated by the addition of rough notes from the books of adversaria of the author.

The correspondence with Leibnitz, which had been resumed in 1688 after a long interruption, went on regularly during the years 1691–5, dealing partly with pure mathematics, partly with the theory of universal gravitation. It shows that Huygens never became reconciled to the use of the differential calculus, but continued to prefer geometrical methods. In 1691 he acknowledges the utility of the calculus, and says that he has made some progress in it; yet in the very last letter to Leibnitz (of December 27, 1694) Huygens remarks that the new method "ne me demeure pas présente à l'esprit quand j'ai discontinué longtemps à m'y exercer." But the numerous letters and notes on the quadrature of curves, especially of the folium of Descartes, exchanged between Marquis de l'Hospital and Huygens show that the latter's power of dealing with geometrical problems was as vigorous as ever. He also continued to correspond with Fatio de Duillier, whose letters foreshadow the accusation of plagiarism which he launched against Leibnitz in 1699, as he from 1691 repeatedly assured Huygens that Newton was the discoverer of the differential calculus, and that it would not be pleasant for Leibnitz if Newton's letters to him were published. Huygens, who continued to think the new calculus unnecessary, did not omit to tell Leibnitz that, according to Fatio, Newton knew more of the inverse problem of tangents than Fatio and Leibnitz did; to which Leibnitz quietly replied that everybody had his own ways of proceeding, and perhaps he knew of some which Newton had not yet perceived. Fatio several times mentioned in his letters that he intended to publish a new edition of the "Principia," as Newton had declined to do it himself, and proposed to expand it into a folio volume, which he flattered himself would be more easily understood than Newton's quarto.

With Leibnitz, Huygens also exchanged ideas about the nature and cause of gravitation. In 1692 Leibnitz remarked that a vortex like that assumed by Descartes is necessary to explain why the earth's axis remains parallel to itself, while the fact that all planets and satellites move in the same direction also points to their being carried along by some fluid matter. He rejects the idea of Cassini, that the orbit of a planet is not an ellipse, but a Cassinian oval, since no physical reason had been given for this hypothesis. The spherical shape of a drop of water, the fall of a body to the earth, and the motion of the planets are all, according to Leibnitz, caused by the "materia ambiens." Huygens, on the other hand, thinks that the sphericity of a drop is more likely caused by the rapid motion of some matter which circulates inside, and as to the planets he fails to see why we should assume the existence of vortices when Newton had proved that the law of inverse squares "with the centrifugal force" produces the ellipses of Kepler. He also makes other objections to the theory of Descartes, particularly to the small spheres of the second element which revolve round the accumulated first element (the sun), and are supposed to have been formed by the corners of the original matter being rubbed off; for if this matter offered any resistance to this rubbing, what should limit the resistance, and if there were none, what should prevent the total destruction of the particles? The vortex which should preserve the parallelism of the earth's axis is incompatible with the motion of the same matter in all directions which should produce gravitation; an objection to which Leibnitz could only reply that we have two such independent circulations here on the earth, causing gravity and magnetism. Huygens acknowledges that vortices are a convenient means of explaining the common direction of planetary motions, but the constant eccentricity of a planet and the variable velocity in the orbit cannot be accounted for by the theory.

In this connection it is most interesting to read some notes written by Huygens to the well known "Vie de Monsieur Descartes," published anonymously by A. Baillet in 1691. According to Huygens, Descartes was very successful in getting his conjectures and fictions accepted as truth, just as novels may be taken for real history; but, on the other hand, he dealt with tangible things, and not with mere words as earlier philosophers had done. Bacon did not understand mathematics and was wanting in penetration as regards physics, being unable even to conceive the possibility of the earth's motion, which he mocked as an absurdity. Galileo had enough of mental power and mathematical knowledge to make progress in physical science, and he was the first to make discoveries as to the nature of motion, although

he left very much to be done. He did not pretend to explain the cause of all natural phenomena, nor had he the vanity to want to be the head of a sect; he was too modest and too great a lover of truth for that. But Descartes wanted to pass for the author of a new philosophy which could take the place of the Aristotelian, and he stuck to what he had once proposed though it was often very wrong. He has done a good deal of harm to the progress of philosophy, for those who believe in him imagine that they know the cause of everything; they waste time in sustaining the doctrines of their master, and do not work to penetrate the real reasons of the great number of phenomena as to which Descartes has only propounded idle fancies. A severe judgment, but not an undeserved one as regards the tenacity with which the followers of the Cartesian philosophy clung to the vortex theory, though it hardly accounted for any of the phenomena of planetary motion.

Probably owing to the infirmities of old age, Huygens during the period covered by this volume did not do any astronomical work, though he wrote to his brother Constantyn in 1693 that he had got a tube made for a 45-feet object glass, chiefly to show the moon and planets to persons of quality who could not manage a tubeless telescope, which was pointed to an object by cords. His interest in the use of pendulum clocks at sea was unabated, and there are several short letters on this subject. As the results of repeated trials were not favourable, Huygens endeavoured to find other means of realising isochronic motion, not subject to disturbance from the rolling of a ship, and designed several forms of balance of which a full account is to appear among his hitherto unpublished works.

There are fewer allusions to current political and other events in this volume than in the previous ones, but naturally the anti-Copernican action of the University of Louvain in 1691 is not passed over. The faculty of arts suspended Prof. van Welden for three years for asserting that the earth was one of the planets. He wrote to Huygens to beg for the intercession of Constantyn Huygens or of King William, but they do not appear to have done anything for him. During the last years of his life, Huygens wrote his well known little book "Cosmotheoros," which was not published until 1698, three years after the death of its author.

J. L. E. D.

PSYCHIATRY.

Manual of Psychiatry. By J. R. de Fursac. Translated by A. J. Rosanoff, and edited by Dr. J. Collins. Pp. xii+352. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1905.) Price 10*s.* 6*d.* net.

THE author has managed to compress a fairly large amount of information into this manual, but we are afraid that the subject-matter is almost too condensed for the reader who is not already conversant with the subject. This book is divided into two parts. The first portion is a general study of the causes, symptoms, and treatment of mental disorder, considered independently of the various affections in which they are encountered. The second portion is devoted to the study of the individual psychoses.

The volume is rather unevenly divided; some subjects are fully dealt with, but the description of others is somewhat meagre. The chapter on ætiology is very good, and this important problem is thoroughly reviewed. We cannot agree with the author in his conclusion that heart disease is common in the insane, and Strecker's figures as to the prevalency of this malady in German asylums, viz. 61.7 per cent for men and 42.7 per cent. for women, would not coincide with similar statistics obtained from English asylums.

In the chapter on general symptomatology the subject of hallucinations and their causation is briefly but well described. Throughout the volume it is very noticeable that purely psychological matters are dealt with in greater detail than other subjects of equal, if not of greater, interest to the practical physician. For example, the pages on treatment are undoubtedly the weakest in the book. Very little space is devoted to this important subject, and the reader is left very much in the dark as to the management of cases of mental disorder.

The author has evidently had the usual difficulty in finding a good classification of insanity. He states that in the absence of one that is founded upon a pathological anatomy basis he has chosen "the most practical, the most convenient, and the one which in any given case would enable us to establish the prognosis and institute the treatment." We quite agree that he has made the best choice in selecting Kraepelin's classification as the basis for his own scheme.

The first chapter in the second part is reserved for the consideration of the "infectious psychoses," of which the following are briefly reviewed:—febrile delirium, infectious delirium, and hydrophobia.

Under the heading of "Psychoses of Exhaustion," the author describes conditions of primary mental confusion and acute delirium. Toxic psychoses are divided into two divisions, (*a*) acute, (*b*) chronic, morphinomania and cocainomania being included in the second class. Dr. de Fursac recommends that, when possible, the rapid method of withdrawal of morphia should be employed in the treatment of morphinism, as he prefers this to the sudden and gradual methods sometimes employed.

The "autointoxication psychoses" include uræmia, the polyneuritic psychosis or Korsakoff's disease, dementia præcox, and general paresis. After thoroughly considering the relationship of syphilis to general paresis, the author states that "at the present time we have no conclusive evidence either for or against the syphilitic origin of general paresis."

The next chapters are devoted to the description of "psychoses dependent upon so-called organic cerebral affections," and "psychoses of involution." The latter include "affective melancholia" and "senile dementia." We do not like the term "affective melancholia"; it seems redundant, for clearly all forms of depression must be affective. Further, the author uses the term in a new sense, which causes

confusion. The chapter on senile dementia is distinctly good and very instructive.

Under "psychoses without a well-determined etiology, which are apparently based upon a morbid predisposition," are found manic-depressive insanity, paranoia, and constitutional psychopathic conditions, such as mental instability, sexual perversions and inversions and obsessions. Paranoia is very briefly described under the title of "Reasoning Insanity." We strongly disagree with the author in his use of this term; it is by no means a good one, and is, in addition, confusing, since other writers have used it as designating the maniacal stage of manic-depressive insanity.

Epilepsy and hysteria are described under the heading of "Psychoses Based on Neuroses," and the concluding chapter is devoted to the consideration of the arrest of mental development.

The book is well translated, and the index is carefully compiled. This manual undoubtedly has its merits, but, as we have already stated, it will scarcely appeal to the practitioner, as the description of treatment is somewhat meagre, and the student will find the subject-matter almost too condensed. In any future edition the author will do well to correct these defects, for by so doing he will render his book a useful manual on psychiatry.

OUR BOOK SHELF.

Experiments with Plants. By Dr. W. J. V. Osterhout. Pp. x+492; illustrated. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1905.) Price 5*s.* net.

THE author defines his aims in the following words (p. 7):—"The numerous questions which young people ask about plants are best answered by themselves. . . . To put them in the way of doing this so far as possible is the object of this book." In accordance with this plan, the apparatus used is of a rough and home-made description, constructed of fruit jars, lamp chimneys, clothes' pegs, india-rubber bands, and sealing-wax. Much ingenuity is shown in the design of apparatus so put together. Whether a sufficient degree of stability is always obtainable may perhaps be questioned, but from the author's point of view the advantages of his method certainly outweigh any such shortcomings. One great merit in the book is the insistence on the necessity of control experiments, which are especially needful with rough methods. The book is divided into chapters headed "The Work of Roots"—of leaves, of stems, &c.—ending up with a chapter on "Making New Kinds of Plants," which is a statement of what breeders and experimenters on variability have done rather than instructions for the making of such experiments.

The author very properly recommends common plants for use; but why students of botany should be confined to such names as "Kentucky Coffee Tree," "Dusty Miller," "Live Forever," "Switch Plant," it is difficult to say. Occasionally we find the scientific name, and in this way we learn that a "Wandering Jew" is a Tradescantia.

Most of the experiments are clearly described, but we have been puzzled over some of them. For instance (p. 191), the method of answering the question, "Does the leaf decompose carbon dioxide?" seems to us to involve passing a lighted candle under water into a jar of air. Here and elsewhere in the book the author neglects simple and striking methods. It is important that the student should be convinced that oxygen is given off by green leaves in light. The above-mentioned experiment is not satisfactory, whereas Engelmann's blood method is both simple and convincing. Again, the well-known plan of counting the bubbles given off by submerged plants in light, though not free from errors, gives useful comparative data for the study of assimilation. In the same way we think that more fundamental experiments should have been given under the heading of "Stomata." Stahl's cobalt method, which is merely mentioned in a note, can be used by the most elementary of students to demonstrate important facts.

In spite of some faults, the book will be found of value to anyone compelled to give a course of physiological botany under conditions which preclude the use of ordinary laboratory fittings.

Conversations on Chemistry. Part i. General Chemistry. By W. Ostwald. Authorised translation by Elizabeth Catherine Ramsay. Pp. v+250. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1905.) Price 6*s.* 6*d.* net.

THE German original of this book has already received sympathetic notice in NATURE, and in connection with the translation now before us it is necessary to add little more than that Miss Ramsay has done her work with much skill, and has made the dialogue not less natural and vivacious than it is in the original. It is impossible to read the book without a feeling of refreshment and amusement, or without admiration of the ingenuity and resource of its philosophical author. It seems hardly fair to say that we have here a revival of Dr. Brewer or Mrs. Marcet. There are two striking differences between the old and the new dialogues. In the first place neither master nor pupil in Prof. Ostwald's book is endowed with that austere and depressing piety of mind which, to the unregenerate, provided perhaps the most afflicting feature of the older works. In the second place Prof. Ostwald's book shows a masterly treatment not only of the real difficulties of chemistry in itself, but a perfect appreciation of the pitfalls that beset the pupil in the early stages of learning. It is difficult to suppose that any teacher will fail to find something useful or to gain some valuable hints from reading the book, and on this ground it must be warmly recommended.

It would, however, be a misfortune if a teacher constrained his teaching to the exact course of the dialogue, and, of course, it would be worse still if he set so many pages as a lesson to be learned by the pupil. The real usefulness of the book will probably lie in the example it affords of the life that may be imparted to teaching when, on the one hand, the pupil is allowed a fair chance of thinking out things for himself and a full opportunity of frankly saying what he thinks, and when, on the other hand, the teacher takes the part of a guide, philosopher, and friend who has a soul above dictionaries and examination papers. A. S.

Mathematical Recreations and Essays. By W. W. Rouse Ball. Fourth edition. Pp. xvi+402. (London: Macmillan and Co., Ltd., 1905.) Price 7*s.* net.

THIS edition differs from the third by containing chapters on the history of the mathematical tripos at Cambridge, Mersenne's numbers, and cryptography and ciphers, besides descriptions of some mathematical recreations previously omitted. The book has thus become more miscellaneous in character, but the additions fit in very well, and are all entertaining. Mr. Ball writes with enjoyment of his subject, and

in a very agreeable style; moreover, he does not assume the reader to possess any knowledge of advanced mathematics. For those who wish to study any of the more important topics in detail he gives ample references; for those merely in search of diversion he provides a mine of amusement, in exploring which many pleasant hours may be spent. And there are some unsolved problems mentioned which the amateur with a mathematical turn of mind may attack with nearly as much chance of success as the expert; for instance, to give a strict proof that only four different colours are necessary to colour a map distinctly. Altogether this is an excellent work of its kind, and ought to find a large number of readers; even those who have a former edition will be likely to buy this one, if only for the sake of the very interesting account of the vicissitudes of the mathematical tripos.

The Rate of Formation of Radium.

THE production of radium from uranium has now been observed experimentally; the rate of production is not, however, in accordance with the quantitative theory. Mr. Soddy's observations (*Phil. Mag.*, June, 1905) gave a rate of production of only one-thousandth of the theoretical amount. An experiment which I made on a specimen of uranium salt, known to be at least thirty years old, has confirmed Mr. Soddy's conclusion so far as to show that the mean rate of production of radium could not have exceeded a hundredth part of the theoretical amount. It may, of course, have been much less, since the amount of radium initially present is unknown.

The explanation of this discrepancy, which has been suggested by Mr. Soddy and others, is that there may be a transitional product. If this is the case, it is to be expected that the rate of production of radium from uranium initially purified will be found to accelerate as time goes on. In the meantime, I am trying an experiment which promises to give the required information more easily.

The transitional product, if it exists, must be contained in pitchblende. If, therefore, we could remove all the radium, but as little else as possible, from a solution of pitchblende, the increased rate of production of radium might be apparent.

Fifty grams of the best pitchblende were dissolved in nitric acid. The insoluble residue was fused with sodium carbonate and added to the solution. The whole was evaporated to small bulk to render silica insoluble; more dilute acid was added, and the silica filtered off and rejected. The metallic bases were thus got into solution.

The solution was freed from radium so far as possible by adding barium nitrate solution in small portions, alternately with equivalent quantities of potassium sulphate. Four and a half grams of the barium salt were thus added. After this the amount of radium remaining was determined by its emanation; three determinations gave, on an arbitrary scale, 69, 58·5, 61·5, mean 63·0. After an interval of three and a half months the amount was again determined. The values were 73·5, 74·5, 72·0, 75·0, 72·5, mean 73·5. It appears probable that this increase is significant, since each of the second series of numbers is larger than any of the first series.

Assuming that the difference is significant, the rate of production per gram of mineral per year would be, on the same scale, 0·723. The equilibrium quantity of radium, the amount, that is, in the untreated mineral, was found to be, per gram, 10,100. If radium decays to one-half its initial quantity in a thousand years, as theory indicates, then the production in one year from a gram of the mineral should be $10,100/1{\cdot}45 \times 1000 = 6{\cdot}9$, about ten times the observed amount.

The increase is insufficient to inspire complete confidence. It seems most probable, however, that there is an increase much greater than in Mr. Soddy's experiments with pure uranium salts. It would not have been difficult to remove all traces of radium, and then the increase (if real) would have been unmistakable. It was feared, however, that the barium precipitation might remove part of the hypothetical intermediate product. It seems likely that this is the case, since the rate of production is still less than theory requires.

A little longer interval will, it is hoped, give a conclusive result. It is intended to try other methods of separating the radium, in the hope of avoiding all loss of the intermediate product.

R. J. STRUTT.

The Effect of Radium on the Strength of Threads.

IN a note which appeared in NATURE on February 4, 1904, Lord Blythswood announced his observation of the destructive action exerted on cambric by the radiation from radium. Having at our disposal recently twenty milligrams of radium bromide which had, for a time, nothing better to do, we investigated the progressive decrease of strength of threads exposed to its influence. In order to have examples of both animal and vegetable fibres, we used unspun silk and ordinary bleached cotton thread.

Ten pieces of thread were exposed at a time. The threads were folded round a strip of writing paper and held in place by being caught in notches cut in the edges of the strip. The paper was laid on the top of the capsule containing the radium, so that the ten threads were exposed to the bare radium at a distance of about half a centimetre. The whole was enclosed in a lead box. After a certain period of exposure the average breaking strength of the threads was taken and plotted against the time. The points obtained lay closely on a smoothly descending curve.

In the case of the silk fibres the loss of strength went on at a practically uniform rate from the beginning up to the longest duration of exposure given (seven days). The initial strength was 78 gms., and this decreased by about 4 gms. per day. The cotton threads, on the other hand, gave a curve which fell more rapidly in the early than in the later stages. The strength began at 370 gms., and decreased at first by about 60 gms. per day. After ten days the rate of weakening was about half this. The longest exposure given was seventeen days; at the end of this time the strength was reduced to 50 gms. The different behaviour of the two kinds of fibres may be due to the much greater thickness of the cotton threads.

The effect seemed to be due entirely to the α rays. A piece of paper was interposed between the threads and the radium, and three days' exposure was given. In the subsequent test none of the threads broke at the exposed part, and the strength was not decreased.

We tried the effect of moistening the cotton threads, the two ends of each thread being left, during a three days' exposure, dipping into a vessel of water. On opening the lead box, in which the whole arrangement was enclosed, it was found that the radium bromide, being hygroscopic, was wet and partially dissolved. The strength of the threads was found to be higher than when exposed in a dry condition for the same period. The difference was too great to be attributed to the increase of strength imparted to threads by moisture, and was plainly due to the decreased emission of rays accompanying the solution, and the consequent removal of the emanation from the radium. We traced the course of the recovery of activity by the dried radium by making a series of three-day exposures of dry threads. The effectiveness of the radiation as measured by the weakening of the threads came back by regular steps in about a fortnight to a value slightly greater than its original one. This may have been due to a re-arrangement of the upper surface of the powder, which was not, at the beginning, very regularly spread over the bottom of the capsule.

HILDA P. MARTIN.
W. B. MORTON.

Queen's College, Belfast, August 8.

AMERICAN RESEARCH IN ASIA.[1]

THIS handsome publication is divided into six sections, Prof. Pumpelly describing the "archeological" and physicogeographical reconnaissance in Turkestan, and Mr. R. W. Pumpelly the physiographic observations on the Pamir; Prof. W. M. Davis describes "a journey across Turkestan," and Mr. Ellsworth Huntington deals with Central Turkestan and with the basin of eastern Persia and Sistan.

The expedition received the most friendly help from the Russian authorities, and received its only check in northern Afghanistan. The dominant factor in the wide region examined appears to be its progressive desiccation, whereby even the irrigation works of the ancient races failed long ago to bring in water from the streams. Everywhere there are signs of old vitality, of great cities, and of peoples who accumulated wealth by trade and settled labour. Again and again, envious invaders from the south, or east, or west, have swept across the hollow lands between the mountains, and have destroyed a civilisation in order to enforce their own. The very sites of the chief towns have shifted, and the remains of the earlier settlements, deeply buried, may afford a clue to "the origin of Western and Eastern civilisations."

Prof. W. M. Davis, experienced in grasping the significance of the surface-features of a country, discusses the former extension of the waters in the Aralo-Caspian area. Particular interest also attaches to his examination of the loess. Whatever the actual origin of this finely divided material, there is no doubt as to its distribution and the moulding of its surface by wind in the eastern provinces of Semiryetshensk and Fergana (p. 63)—we adopt the spelling of the text, and not of the map which forms plate iii. Mr. Huntington also observes loess in process of formation in the Kashgar plain, and refers it here to the spreading out of very fine silt by water in the flat floor of temporary and recurrent lakes. There is in reality no contradiction between these views, since most writers are agreed that the material gathers first of all in the plains by ordinary processes of denudation, and then undergoes further sifting, the chief agent being the persistent action of the wind.

Both these authors believe that the Tian Shan mountains were worn down to a fairly uniform surface after their principal folding had occurred, and that they owe their present irregular surface more to subsequent differential uplifts than to denudation (pp. 73, 80, 168, &c.). "Even in the lofty Pamir there are certain ranges where the snowy peaks are smoothly truncated, as though by the old peneplain, in spite of the fact that they are from 15,000 to 20,000 feet high." Prof. Davis seems not to insist on so recent a date for the "peneplain" as does his colleague, who brings forward conclusive evidence that the whole Tertiary series of the district was involved in the folding, and that the uniform degradation must be assigned to late Tertiary times. The present development of the "peneplain" in Central Turkestan seems, according to Mr. Huntington, due to the formation of ridges and basins, without conspicuous faulting. Prof. Davis, on his part, lays more stress on faults and "fault-blocks." Lateral compression, he urges, has had little to do with the raising of the block-ranges, to which our attention is now for the first time directed in this area; and he proceeds, in consequence, to consider the bearing of the Tian Shan ranges on Suess's views on horsts. He justly remarks (p. 82) that "forces of uplift are

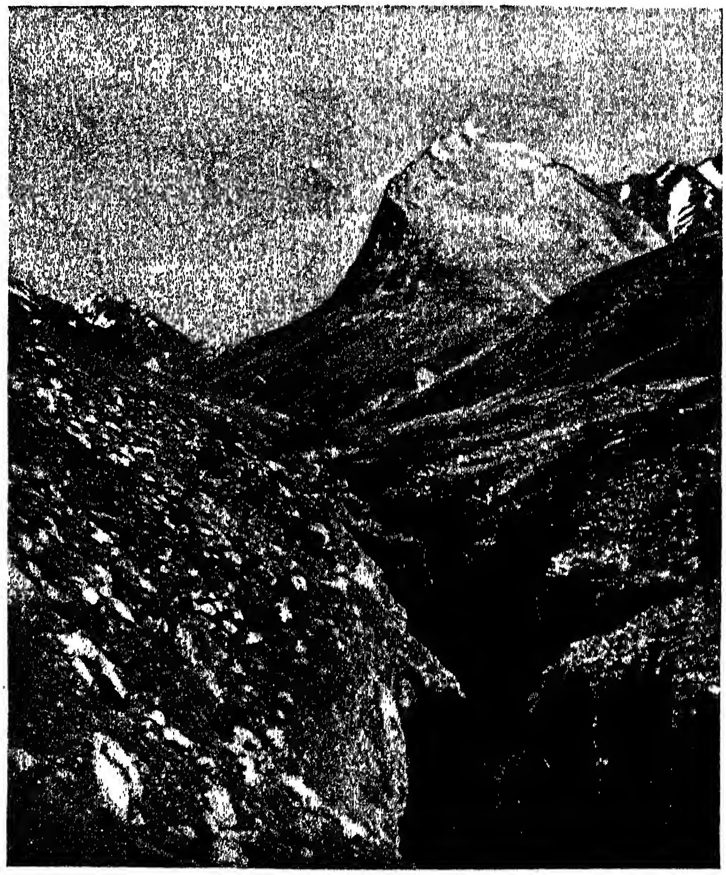

FIG. 1.—Youngest Gorge of the Khoja Ishken, cut in the bottom of the main Glacial Valley. From "Explorations in Turkestan, with an Account of the Basin of Eastern Persia and Sistan."

still worthy of consideration"; and, being himself a profound student of processes of denudation, he points out that the surfaces of many horsts must have been near sea-level before they were separated by dislocation. After all, may we not be grateful to Suess when we find discussions such as these arising naturally in a work of travel, which might in some hands have been a record of detached geological observations?

The glacial phenomena of the central ranges are described in connection with the successive areas studied, and the gravel terraces, which are well illustrated by views and sections, are correlated with climatic changes. The authors hope that subsequent

[1] "Explorations in Turkestan, with an Account of the Basin of Eastern Persia and Sistan." Expedition of the Carnegie Institution of Washington in 1903, under the direction of Raphael Pumpelly. Pp. xii+324; with map plates, and figures in the text. (Washington: Carnegie Institution, 1905.)

researches may indicate fluctuations in the Aralo-Caspian waters, in correspondence with those traceable in the rivers that flowed down from the glaciated areas. Mr. R. W. Pumpelly tried, in the short time at his disposal, to correlate (p. 143) the glacial changes with the successive shorelines traceable in the basin of Kara Kul on the Pamir, and makes the interesting suggestion that this lake rose to a height of 320 feet or more above its present level during the first local glacial epoch, and to a height of 150 feet during the second epoch, the times of greatest precipitation corresponding with the increase in the lacustrine waters. Both here and in the Alai Valley to the north, two well marked series of moraines exist. The older series in the Alai Valley is clearly indicated by being cut into by the narrower valley-troughs, with which the second and fresher series is associated. If we read Mr. Pumpelly aright—for his mode of bringing together his observations leaves something to be desired and explained—the older glacial epoch actually preceded some of the earth-movements which gave the ranges their present relations and elevations (pp. 145 and 155).

Mr. Huntington goes so far as the presentation of five glacial epochs, on the evidence of the large and high-reaching valleys which still contain glaciers in them (p. 199); and, arguing from the very probable

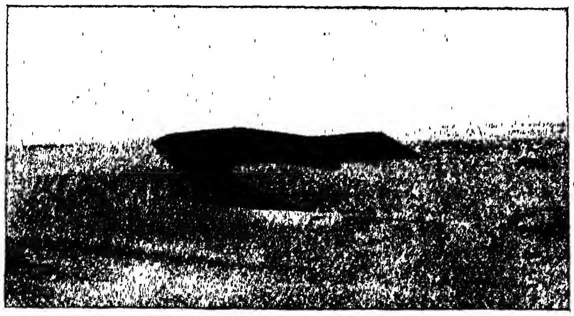

FIG. 2.—A Barkhan near Bakharden, looking south. From "Explorations in Turkestan, with an Account of the Basin of Eastern Persia and Sistan."

correlation of his epochs of gravel-deposition and of glacial extension higher up the country, he is inclined to ask for at least six advances and six considerable "interglacial" withdrawals of the ice. In his concluding paper on eastern Persia and Sistan, he describes what he styles "one of the most desolate lands in the world," "a land of gravel and nakedness, of huge desert basins and desolate, interminable slopes, of tantalizing mirages and bare mountains." The average rainfall does not rise above 10 inches, and comes from the south-east; while the summer wind from the north, often as violent as a hurricane, fills the air for four arid months with continental dust. The country is dealt with by Mr. Huntington as by a scientific artist, and his picturesque touch is emphasised by an occasional aphorism, such as "The desert makes men lose every sentiment except the desire to get safely to the other side." Persia is to him a "typical example of an arid country"; and he gives us a fine sketch of its life-history. He then describes in detail five series of recent river-terraces, and connects them, as we are led by this time to expect, with climatic changes, similar to those in Turkestan. The alternations in the lake-deposits of Sistan then come in for corresponding treatment, and the decay of the area in population and in political power in modern times is attributed to the final desiccation.

We are glad that Mr. Huntington's clearly written papers close the series; for must we not admit that American physical geographers, who are apt to classify old conceptions until they appear to develop into new ones, provide us at times with somewhat difficult reading? On p. 79 we have:—"the peneplanation of the region improved in the final 40 miles of the road on the sixth day. In the morning some of the broad ridges . . . were from 300 to 500 feet over the intervales." Mr. Pumpelly can hardly be a cyclist, or he would not speak of "deflated bowlders" on p. 131. If, again, we all understand what dating a letter means, how shall we appreciate the phrase (p. 135) "the epochs predating the escarpments"? We make these remarks as much in the interest of the conscientious foreigner as of ourselves; for the directors of the publications of the Carnegie Institution have no right and no desire to remain content with a purely American circulation.

As examples of the numerous effective illustrations, we may mention the photograph of a characteristic crescent-shaped "barkhan" of blown sand on p. 44, and that of the glacial valley and subsequent ravine of the Khoja Ishken on p. 188, both of which are here reproduced; but all throughout are to the purpose, even when merely showing modes of travel in a region of absorbing interest.

GRENVILLE A. J. COLE.

HABITS OF BIRDS.[1]

MR. EDMUND SELOUS, the author of this elegant little volume, is one of the most patient and enthusiastic observers of bird-life in the British Islands, and has recorded details in connection with the habits of several species which have been overlooked by other field-naturalists. If the riddle of nature is ever to be solved by observations on living animals, Mr. Selous is one of the men who ought to help to solve it, although we are bound to confess that several of his theories, notably the one with regard to the origin of the nest-making instinct, do not appear to ourselves by any means convincing or sufficient. Nests, indeed, form a very favourite theme of the author; so much so, in fact, that when discussing the building of supernumerary nests by various species on pp. 67 and 199, he practically repeats the same thing, namely, that this results, originally, from a simple love of labour and occupation.

The author is, perhaps, at his best when describing the movements and actions of birds as seen during his inimitably patient watchings, excellent examples of this being shown in his description of herons alighting on their nest, and of long-tailed titmice constructing the domed receptacle in which their eggs are deposited. The latter incident is represented in one of the illustrations, photographed, like the rest, from a sketch by the clever pencil of Mr. Lodge, this exquisite picture being reproduced as a sample of the illustrations generally. As an interesting suggestion, reference may be made to the author's theory that when a woodpecker's nesting hole has been usurped by a starling, the rightful owner may occasionally lay an egg in the nest, and that in this manner the parasitic habit of the cuckoo may have been developed. The fact of starlings excavating large nesting chambers in sand-cliffs is entirely new to us.

In regard to the "get-up" of the book, we may suggest that it would have been an improvement if, instead of repeating the main title as the heading for alternate pages, the name of the species under dis-

[1] "Bird Life Glimpses." By E. Selous. Pp. viii+335; illustrated. (London: G. Allen, 1905.) Price 6s. net.

cussion had been given, for, in consequence of the vague headings on the opposite pages, it is often a matter of some little difficulty to discover to which particular bird the author is referring. Throughout his volume Mr. Selous is fond of interpolating phrases or quotations in foreign languages, inclusive of French, German, Latin, and Greek. Whether such a practice is altogether desirable may be a matter of opinion, but there will be only one opinion as to the desirability of quoting correctly, which is far from being the case when a well-known line from the second book of the Æneid is introduced on p. 109.

FIG. 1.—Long-tailed Tits and the Nest. From E. Selous's "Bird Life Glimpses."

THE SOUTH AFRICAN MEETING OF THE BRITISH ASSOCIATION.

THE seventy-fifth meeting of the British Association was inaugurated at Cape Town on Tuesday, when the president, Prof. G. H. Darwin, F.R.S., delivered the first portion of his address to a large gathering in the new City Hall. This part is reprinted below, and the remainder of the address, to be delivered at Johannesburg on Wednesday, August 30, will appear in NATURE of the following day.

From a Reuter message we learn that on the conclusion of the address, the Governor, Sir Walter Hely-Hutchinson, in proposing a vote of thanks, bade the association heartily welcome on behalf of Cape Colony. The occasion was one, he said, of no ordinary importance, whether in the history of the development of scientific inquiry or in the history of the relations of the United Kingdom with the British dominions beyond the seas. He hoped it would be found that a great and important step had been taken in drawing closer together the bonds of the brotherhood of science, and, it might be, through the brotherhood of science, in promoting and developing brotherly feeling between His Majesty's subjects in South Africa and the Motherland.

Sir David Gill, K.C.B., chairman of the central organising committee at Cape Town, seconded the motion; and a brief reply by Prof. Darwin brought the proceedings to a close.

The addresses of all the presidents of sections were to be delivered yesterday on the assembling of the sections at Cape Town. The sections are also to meet for the reading and discussion of reports and papers to-day and to-morrow, and they will reassemble on Tuesday, August 29, at Johannesburg, where the concluding meeting will be held on September 1, and the work of the sections will terminate.

INAUGURAL ADDRESS BY PROF. G. H. DARWIN, M.A., LL.D., PH.D., F.R.S., PRESIDENT OF THE ASSOCIATION.

PART I.

BARTHOLOMEU DIAZ, the discoverer of the Cape of Storms, spent sixteen months on his voyage, and the little flotilla of Vasco da Gama, sailing from Lisbon on July 8, 1497, only reached the Cape in the middle of November. These bold men, sailing in their puny fishing smacks to unknown lands, met the perils of the sea and the attacks of savages with equal courage. How great was the danger of such a voyage may be gathered from the fact that less than half the men who sailed with da Gama lived to return to Lisbon. Four hundred and eight years have passed since that voyage, and a ship of 13,000 tons has just brought us here, in safety and luxury, in but little more than a fortnight.

How striking are the contrasts presented by these events! On the one hand compare the courage, the endurance, and the persistence of the early navigators with the little that has been demanded of us; on the other hand consider how much man's power over the forces of nature has been augmented during the past four centuries. The capacity for heroism is probably undiminished, but certainly the occasions are now rarer when it is demanded of us. If we are heroes, at least but few of us ever find it out, and, when we read stories of ancient feats of courage, it is hard to prevent an uneasy thought that, notwithstanding our boasted mechanical inventions, we are perhaps degenerate descendants of our great predecessors.

Yet the thought that to-day is less romantic and less heroic than yesterday has its consolation, for it means,

that the lot of man is easier than it was. Mankind, indeed, may be justly proud that this improvement has been due to the successive efforts of each generation to add to the heritage of knowledge handed down to it by its predecessors, whereby we have been born to the accumulated endowment of centuries of genius and labour.

I am told that in the United States the phrase "I want to know" has lost the simple meaning implied by the words, and has become a mere exclamation of surprise. Such a conventional expression could hardly have gained currency except amongst a people who aspire to knowledge. The dominance of the European race in America, Australasia, and South Africa has no doubt arisen from many causes, but amongst these perhaps the chief one is that not only do "we want to know," but also that we are determined to find out. And now within the last quarter of a century we have welcomed into the ranks of those who "want to know" an oriental race, which has already proved itself strong in the peaceful arts of knowledge.

I take it, then, that you have invited us because you want to know what is worth knowing; and we are here because we want to know you, to learn what you have to tell us, and to see that South Africa of which we have heard so much.

The hospitality which you are offering us is so lavish, and the journeys which you have organised are so extensive, that the cynical observer might be tempted to describe our meeting as the largest picnic on record. Although we intend to enjoy our picnic with all our hearts, yet I should like to tell the cynic, if he is here, that perhaps the most important object of these conferences is the opportunity they afford for personal intercourse between men of like minds who live at the remotest corners of the earth.

We shall pass through your land with the speed and the voracity of a flight of locusts; but, unlike the locust, we shall, I hope, leave behind us permanent fertilisation in the form of stimulated scientific and educational activity. And this result will ensue whether or not we who have come from Europe are able worthily to sustain the lofty part of prophets of science. We shall try our best to play to your satisfaction on the great stage upon which you call on us to act, and if when we are gone you shall, amongst yourselves, pronounce the performance a poor one, yet the fact will remain, that this meeting has embodied in a material form the desire that the progress of this great continent shall not be merely material; and such an aspiration secures its own fulfilment. However small may be the tangible results of our meeting, we shall always be proud to have been associated with you in your efforts for the advancement of science.

We do not know whether the last hundred years will be regarded for ever as the *saeculum mirabile* of discovery, or whether it is but the prelude to yet more marvellous centuries. To us living men, who scarcely pass a year of our lives without witnessing some new marvel of discovery or invention, the rate at which the development of knowledge proceeds is truly astonishing; but from a wider point of view the scale of time is relatively unimportant, for the universe is leisurely in its procedure. Whether the changes which we witness be fast or slow, they form a part of a long sequence of events which begin in some past of immeasurable remoteness and tend to some end which we cannot foresee. It must always be profoundly interesting to the mind of man to trace successive cause and effect in the chain of events which make up the history of the earth and all that lives on it, and to speculate on the origin and future fate of animals, and of planets, suns, and stars. I shall try, then, to set forth in my address some of the attempts which have been made to formulate evolutionary speculation. This choice of a subject has, moreover, been almost forced on me by the scope of my own scientific work, and it is, I think, justified by the name which I bear. It will be my fault and your misfortune if I fail to convey to you some part of the interest which is naturally inherent in such researches.

The man who propounds a theory of evolution is attempting to reconstruct the history of the past by means of the circumstantial evidence afforded by the present. The historian of man, on the other hand, has the advantage over the evolutionist in that he has the written records of the past on which to rely. The discrimination of the truth from amongst discordant records is frequently a work demanding the highest qualities of judgment; yet when this end is attained it remains for the historian to convert the arid skeleton of facts into a living whole by clothing it with the flesh of human motives and impulses. For this part of his task he needs much of that power of entering into the spirit of other men's lives which goes to the making of a poet. Thus the historian should possess not only the patience of the man of science in the analysis of facts, but also the imagination of the poet to grasp what the facts have meant. Such a combination is rarely to be found in equal perfection on both sides, and it would not be hard to analyse the works of great historians so as to see which quality was predominant in each of them.

The evolutionist is spared the surpassing difficulty of the human element, yet he also needs imagination, although of a different character from that of the historian. In its lowest form his imagination is that of the detective who reconstructs the story of a crime; in its highest it demands the power of breaking loose from all the trammels of convention and education, and of imagining something which has never occurred to the mind of man before. In every case the evolutionist must form a theory for the facts before him, and the great theorist is only to be distinguished from the fantastic fool by the sobriety of his judgment—a distinction, however, sufficient to make one rare and the other only too common.

The test of a scientific theory lies in the number of facts which it groups into a connected whole; it ought besides to be fruitful in pointing the way to the discovery and coordination of new and previously unsuspected facts. Thus a good theory is in effect a cyclopædia of knowledge, susceptible of indefinite extension by the addition of supplementary volumes.

Hardly any theory is all true, and many are not all false. A theory may be essentially at fault and yet point the way to truth, and so justify its temporary existence. We should not, therefore, totally reject one or other of two rival theories on the ground that they seem, with our present knowledge, mutually inconsistent, for it is likely that both may contain important elements of truth. The theories of which I shall have to speak hereafter may often appear discordant with one another according to our present lights. Yet we must not scruple to pursue the several divergent lines of thought to their logical conclusions, relying on future discovery to eliminate the false and to reconcile together the truths which form part of each of them.

In the mouths of the unscientific evolution is often spoken of as almost synonymous with the evolution of the various species of animals on the earth, and this again is sometimes thought to be practically the same thing as the theory of natural selection. Of course those who are conversant with the history of scientific ideas are aware that a belief in the gradual and orderly transformation of nature, both animate and inanimate, is of great antiquity.

We may liken the facts on which theories of evolution are based to a confused heap of beads, from which a keen-sighted searcher after truth picks out and strings together a few which happen to catch his eye, as possessing certain resemblances. Until recently, theories of evolution in both realms of nature were partial and discontinuous, and the chains of facts were correspondingly short and disconnected. At length the theory of natural selection, by formulating the cause of the divergence of forms in the organic world from the parental stock, furnished the naturalist with a clue by which he examined the disordered mass of facts before him, and he was thus enabled to go far in deducing order where chaos had ruled before; but the problem of reducing the heap to perfect order will probably baffle the ingenuity of the investigator for ever.

So illuminating has been this new idea that, as the whole of nature has gradually been re-examined by its aid, thousands of new facts have been brought to light, and have been strung in due order on the necklace of knowledge. Indeed, the transformation resulting from the new

point of view has been so far-reaching as almost to justify the misapprehension of the unscientific as to the date when the doctrines of evolution first originated in the mind of man.

It is not my object, nor indeed am I competent, to examine the extent to which the theory of natural selection has needed modification since it was first formulated by my father and Wallace. But I am surely justified in maintaining that the general principle holds its place firmly as a permanent acquisition to modes of thought.

Evolutionary doctrines concerning inanimate nature, although of much older date than those which concern life, have been profoundly affected by the great impulse of which I have spoken. It has thus come about that the origin and history of the chemical elements and of stellar systems now occupy a far larger space in the scientific mind than was formerly the case. The subject which I shall discuss to-night is the extent to which ideas, parallel to those which have done so much towards elucidating the problems of life, hold good also in the world of matter; and I believe that it will be possible to show that in this respect there exists a resemblance between the two realms of nature, which is not merely fanciful. It is proper to add that so long ago as 1873 Baron Karl du Prel discussed the same subject from a similar point of view, in a book entitled "The Struggle for Life in the Heavens."[1]

Although inanimate matter moves under the action of forces which are incomparably simpler than those governing living beings, yet the problems of the physicist and the astronomer are scarcely less complex than those which present themselves to the biologist. The mystery of life remains as impenetrable as ever, and in his evolutionary speculations the biologist does not attempt to explain life itself, but, adopting as his unit the animal as a whole, discusses its relationships to other animals and to the surrounding conditions. The physicist, on the other hand, is irresistibly impelled to form theories as to the intimate constitution of the ultimate parts of matter, and he desires further to piece together the past histories and the future fates of planets, stars, and nebulæ. If then the speculations of the physicist seem in some respects less advanced than those of the biologist, it is chiefly because he is more ambitious in his aims. Physicists and astronomers have not yet found their Johannesburg or Kimberley; but although we are still mere prospectors, I am proposing to show you some of the dust and diamonds which we have already extracted from our surface mines.

The fundamental idea in the theory of natural selection is the persistence of those types of life which are adapted to their surrounding conditions, and the elimination by extermination of ill-adapted types. The struggle for life amongst forms possessing a greater or less degree of adaptation to slowly varying conditions is held to explain the gradual transmutation of species. Although a different phraseology is used when we speak of the physical world, yet the idea is essentially the same.

The point of view from which I wish you to consider the phenomena of the world of matter may be best explained if, in the first instance, I refer to political institutions, because we all understand, or fancy we understand, something of politics, whilst the problems of physics are commonly far less familiar to us. This illustration will have a further advantage in that it will not be a mere parable, but will involve the fundamental conception of the nature of evolution.

The complex interactions of man with man in a community are usually described by such comprehensive terms as the State, the Commonwealth, or the Government. Various States differ widely in their constitution and in the degree of the complexity of their organisation, and we classify them by various general terms, such as autocracy, aristocracy, or democracy, which express somewhat loosely their leading characteristics. But, for the purpose of showing the analogy with physics, we need terms of wider import than those habitually used in politics. All forms of the State imply inter-relationship in the actions of men, and action implies movement. Thus the State may be described as a configuration or arrangement of a community of men; or we may say that it implies a definite mode of motion of man—that is to say, an organised scheme of action of man on man. Political history gives an account of the gradual changes in such configurations or modes of motion of men as have possessed the quality of persistence or of stability to resist the disintegrating influence of surrounding circumstances.

In the world of life the naturalist describes those forms which persist as species; similarly the physicist speaks of stable configurations or modes of motion of matter; and the politician speaks of States. The idea at the base of all these conceptions is that of stability, or the power of resisting disintegration. In other words, the degree of persistence or permanence of a species, of a configuration of matter, or of a State depends on the perfection of its adaptation to its surrounding conditions.

If we trace the history of a State we find the degree of its stability gradually changing, slowly rising to a maximum, and then slowly declining. When it falls to nothing a revolution ensues, and a new form of government is established. The new mode of motion or government has at first but slight stability, but it gradually acquires strength and permanence, until in its turn the slow decay of stability leads on to a new revolution.

Such crises in political history may give rise to a condition in which the State is incapable of perpetuation by transformation. This occurs when a savage tribe nearly exterminates another tribe and leads the few survivors into slavery; the previous form of government then becomes extinct.

The physicist, like the biologist and the historian, watches the effect of slowly varying external conditions; he sees the quality of persistence or stability gradually decaying until it vanishes, when there ensues what is called, in politics, a revolution.

These considerations lead me to express a doubt whether biologists have been correct in looking for continuous transformation of species. Judging by analogy, we should rather expect to find slight continuous changes occurring during a long period of time, followed by a somewhat sudden transformation into a new species, or by rapid extinction. However this may be, when the stability of a mode of motion vanishes, the physicist either finds that it is replaced by a new persistent type of motion adapted to the changed conditions, or perhaps that no such transformation is possible, and that the mode of motion has become extinct. The evanescent type of animal life has often been preserved for us, fossilised in geological strata; the evanescent form of government is preserved in written records or in the customs of savage tribes; but the physicist has to pursue his investigations without such useful hints as to the past.

The time-scale in the transmutation of species of animals is furnished by the geological record, although it is not possible to translate that record into years. As we shall see hereafter, the time needed for a change of type in atoms or molecules may be measured by millionths of a second, while in the history of the stars continuous changes may occupy millions of years. Notwithstanding this gigantic contrast in speed, yet the process involved seems to be essentially the same.

It is hardly too much to assert that, if the conditions which determine stability of motion could be accurately formulated throughout the universe, the past history of the cosmos and its future fate would be unfolded. How indefinitely far we stand removed from such a state of knowledge will become abundantly clear from the remainder of my address.

The study of stability and instability then furnishes the problems which the physicist and biologist alike attempt to solve. The two classes of problems differ principally in the fact that the conditions of the world of life are so incomparably more intricate than those of the world of matter that the biologist is compelled to abandon the attempt to determine the absolute amount of the influence of the various causes which have affected the existence of species. His conclusions are merely qualitative and general, and he is almost universally compelled to refrain from asserting even in general terms what are the reasons which have rendered one form of animal life stable and persistent, and another unstable and evanescent.

On the other hand, the physicist, as a general rule,

[1] "Der Kampf um's Dasein am Himmel." Zweite Auflage. (Berlin: Denicke, 1876.)

does not rest satisfied unless he obtains a quantitative estimate of various causes and effects on the systems of matter which he discusses. Yet there are some problems of physical evolution in which the conditions are so complex that the physicist is driven, as is the biologist, to rest satisfied with qualitative rather than quantitative conclusions. But he is not content with such crude conclusions except in the last resort, and he generally prefers to proceed by a different method.

The mathematician mentally constructs an ideal mechanical system or model, which is intended to represent in its leading features the system he wants to examine. It is often a task of the utmost difficulty to devise such a model, and the investigator may perchance unconsciously drop out as unimportant something which is really essential to represent actuality. He next examines the conditions of his ideal system, and determines, if he can, all the possible stable and unstable configurations, together with the circumstances which will cause transitions from one to the other. Even when the working model has been successfully imagined, this latter task may often overtax the powers of the mathematician. Finally it remains for him to apply his results to actual matter, and to form a judgment of the extent to which it is justifiable to interpret nature by means of his results.

The remainder of my address will be occupied by an account of various investigations which will illustrate the principles and methods which I have now explained in general terms.

The fascinating idea that matter of all kinds has a common substratum is of remote antiquity. In the Middle Ages the alchemists, inspired by this idea, conceived the possibility of transforming the baser metals into gold. The sole difficulty seemed to them the discovery of an appropriate series of chemical operations. We now know that they were always indefinitely far from the goal of their search, yet we must accord to them the honour of having been the pioneers of modern chemistry.

The object of alchemy, as stated in modern language, was to break up or dissociate the atoms of one chemical element into its component parts, and afterwards to reunite them into atoms of gold. Although even the dissociative stage of the alchemistic problem still lies far beyond the power of the chemist, yet modern researches seem to furnish a sufficiently clear idea of the structure of atoms to enable us to see what would have to be done to effect a transformation of elements. Indeed, in the complex changes which are found to occur spontaneously in uranium, radium, and the allied metals we are probably watching a spontaneous dissociation and transmutation of elements.

Natural selection may seem, at first sight, as remote as the poles asunder from the ideas of the alchemist, yet dissociation and transmutation depend on the instability and regained stability of the atom, and the survival of the stable atom depends on the principle of natural selection.

Until some ten years ago the essential diversity of the chemical elements was accepted by the chemist as an ultimate fact, and indeed the very name of atom, or that which cannot be cut, was given to what was supposed to be the final indivisible portion of matter. The chemist thus proceeded in much the same way as the biologist who, in discussing evolution, accepts the species as his working unit. Accordingly, until recently the chemist discussed working models of matter of atomic structure, and the vast edifice of modern chemistry has been built with atomic bricks.

But within the last few years the electrical researches of Lenard, Röntgen, Becquerel, the Curies, of my colleagues Larmor and Thomson, and of a host of others, have shown that the atom is not indivisible, and a flood of light has been thrown thereby on the ultimate constitution of matter. Amongst all these fertile investigators it seems to me that Thomson stands preeminent, because it is principally through him that we are to-day in a better position for picturing the structure of an atom than was ever the case before.

Even if I had the knowledge requisite for a complete exposition of these investigations, the limits of time would compel me to confine myself to those parts of the subject which bear on the constitution and origin of the elements.

It has been shown, then, that the atom, previously supposed to be indivisible, really consists of a large number of component parts. By various convergent lines of experiment it has been proved that the simplest of all atoms, namely that of hydrogen, consists of about 800 separate parts; while the number of parts in the atom of the denser metals must be counted by tens of thousands. These separate parts of the atom have been called corpuscles or electrons, and may be described as particles of negative electricity. It is paradoxical, yet true, that the physicist knows more about these ultra-atomic corpuscles and can more easily count them than is the case with the atoms of which they form the parts.

The corpuscles, being negatively electrified, repel one another just as the hairs on a person's head mutually repel one another when combed with a vulcanite comb. The mechanism is as yet obscure whereby the mutual repulsion of the negative corpuscles is restrained from breaking up the atom, but a positive electrical charge, or something equivalent thereto, must exist in the atom, so as to prevent disruption. The existence in the atom of this community of negative corpuscles is certain, and we know further that they are moving with speeds which may in some cases be comparable to the velocity of light, namely, 200,000 miles a second. But the mechanism whereby they are held together in a group is hypothetical.

It is only just a year ago that Thomson suggested, as representing the atom, a mechanical or electrical model the properties of which could be accurately examined by mathematical methods. He would be the first to admit that his model is at most merely a crude representation of actuality, yet he has been able to show that such an atom must possess mechanical and electrical properties which simulate, with what Whetham describes as "almost Satanic exactness," some of the most obscure and yet most fundamental properties of the chemical elements. "Se non è vero, è ben trovato," and we are surely justified in believing that we have the clue which the alchemists sought in vain.

Thomson's atom consists of a globe charged with positive electricity, inside which there are some thousand or thousands of corpuscles of negative electricity, revolving in regular orbits with great velocities. Since two electrical charges repel one another if they are of the same kind, and attract one another if they are of opposite kinds, the corpuscles mutually repel one another, but all are attracted by the globe containing them. The forces called into play by these electrical interactions are clearly very complicated, and you will not be surprised to learn that Thomson found himself compelled to limit his detailed examination of the model atom to one containing about seventy corpuscles. It is indeed a triumph of mathematical power to have determined the mechanical conditions of such a miniature planetary system as I have described.

It appears that in general there are definite arrangements of the orbits in which the corpuscles must revolve, if they are to be persistent or stable in their motions. But the number of corpuscles in such a community is not absolutely fixed. It is easy to see that we might add a minor planet, or indeed half a dozen minor planets, to the solar system without any material derangement of the whole; but it would not be possible to add a hundred planets with an aggregate mass equal to that of Jupiter without disorganisation of the solar system. So also we might add or subtract from an atom three or four corpuscles from a system containing a thousand corpuscles moving in regular orbits without any profound derangement. As each arrangement of orbits corresponds to the atom of a distinct element, we may say that the addition or subtraction of a few corpuscles to the atom will not effect a transmutation of elements. An atom which has a deficiency of its full complement of corpuscles, which it will be remembered are negative, will be positively electrified, while one with an excess of corpuscles will be negatively electrified. I have referred to the possibility of a deficiency or excess of corpuscles because it is important in Thomson's theory; but, as it is not involved in the point of view which I wish to take, I will henceforth only refer to the normal or average number in any arrange-

ment of corpuscles. Accordingly we may state that definite numbers of corpuscles are capable of association in stable communities of definite types.

An infinite number of communities are possible, possessing greater or lesser degrees of stability. Thus the corpuscles in one such community might make thousands of revolutions in their orbits before instability declared itself; such an atom might perhaps last for a long time as estimated in millionths of seconds, but it must finally break up and the corpuscles must disperse or re-arrange themselves after the ejection of some of their number. We are thus led to conjecture that the several chemical elements represent those different kinds of communities of corpuscles which have proved by their stability to be successful in the struggle for life. If this is so, it is almost impossible to believe that the successful species have existed for all time, and we must hold that they originated under conditions about which I must forbear to follow Sir Norman Lockyer in speculating.[1]

But if the elements were not eternal in the past, we must ask whether there is reason to believe that they will be eternal in the future. Now, although the conception of the decay of an element and its spontaneous transmutation into another element would have seemed absolutely repugnant to the chemist until recently, yet analogy with other moving systems seems to suggest that the elements are not eternal.

At any rate it is of interest to pursue to its end the history of the model atom which has proved to be so successful in imitating the properties of matter. The laws which govern electricity in motion indicate that such an atom must be radiating or losing energy, and therefore a time must come when it will run down, as a clock does. When this time comes it will spontaneously transmute itself into an element which needs less energy than was required in the former state. Thomson conceives that an atom might be constructed after his model so that its decay should be very slow. It might, he thinks, be made to run for a million years, but it would not be eternal.

Such a conclusion is an absolute contradiction to all that was known of the elements until recently, for no symptoms of decay are perceived, and the elements existing in the solar system must already have lasted for millions of years. Nevertheless, there is good reason to believe that in radium, and in other elements possessing very complex atoms, we do actually observe that break-up and spontaneous re-arrangement which constitute a transmutation of elements.

It is impossible as yet to say how science will solve this difficulty, but future discovery in this field must surely prove deeply interesting. It may well be that the train of thought which I have sketched will ultimately profoundly affect the material side of human life, however remote it may now seem from our experiences of daily life.

I have not as yet made any attempt to represent the excessive minuteness of the corpuscles, of the existence of which we are now so confident; but, as an introduction to what I have to speak of next, it is necessary to do so. To obtain any adequate conception of their size we must betake ourselves to a scheme of threefold magnification. Lord Kelvin has shown that, if a drop of water were magnified to the size of the earth, the molecules of water would be of a size intermediate between that of a cricket-ball and of a marble. Now each molecule contains three atoms, two being of hydrogen and one of oxygen. The molecular system probably presents some sort of analogy with that of a triple star; the three atoms, replacing the stars, revolving about one another in some sort of dance which cannot be exactly described. I doubt whether it is possible to say how large a part of the space occupied by the whole molecule is occupied by the atoms; but perhaps the atoms bear to the molecule some such relationship as the molecule to the drop of water referred to. Finally, the corpuscles may stand to the atom in a similar scale of magnitude. Accordingly a threefold magnification would be needed to bring these ultimate parts of the atom within the range of our ordinary scales of measurement.

I have already considered what would be observed under the triply powerful microscope, and must now return to the intermediate stage of magnification, in which we consider those communities of atoms which form molecules. This is the field of research of the chemist. Although prudence would tell me that it would be wiser not to speak of a subject of which I know so little, yet I cannot refrain from saying a few words.

[1] "Inorganic Evolution." (Macmillan, 1900.)

The community of atoms in water has been compared with a triple star, but there are others known to the chemist in which the atoms are to be counted by fifties and hundreds, so that they resemble constellations.

I conceive that here again we meet with conditions similar to those which we have supposed to exist in the atom. Communities of atoms are called chemical combinations, and we know that they possess every degree of stability. The existence of some is so precarious that the chemist in his laboratory can barely retain them for a moment; others are so stubborn that he can barely break them up. In this case dissociation and re-union into new forms of communities are in incessant and spontaneous progress throughout the world. The more persistent or more stable combinations succeed in their struggle for life, and are found in vast quantities, as in the cases of common salt and of the combinations of silicon. But no one has ever found a mine of gun-cotton, because it has so slight a power of resistance. If, through some accidental collocation of elements, a single molecule of gun-cotton were formed, it would have but a short life.

Stability is, further, a property of relationship to surrounding conditions; it denotes adaptation to environment. Thus salt is adapted to the struggle for existence on the earth, but it cannot withstand the severer conditions which exist in the sun.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. A. R. FORSYTH, SC.D., LL.D., MATH.D., F.R.S., PRESIDENT OF THE SECTION.

ACCORDING to an established and unchallenged custom, our proceedings are inaugurated by an address from the President. Let me begin it by discharging a duty which, unhappily, is of regular recurrence. If your President only mentions names when he records the personal losses suffered during the year by the sciences of the Section, the corporate sense of the Section will be able to appreciate the losses with a deeper reality than can be conveyed by mere words.

In Mr. Ronald Hudson, who was one of our secretaries at the Cambridge meeting a year ago, we have lost a mathematician whose youthful promise had ripened into early performance. The original work which he had accomplished is sufficient, both in quality and in amount, to show that much has been given, and that much more could have been expected. His alert and bright personality suggested that many happy years lay before him. All these fair hopes were shattered in a moment by an accident upon a Welsh hillside; and his friends, who were many, deplore his too early death at the age of twenty-eight.

The death of Mr. Frank McClean has robbed astronomy of one of its most patient workers and actively creative investigators. I wish that my own knowledge could enable me to give some not inadequate exposition of his services to the science which he loved so well. He was a man of great generosity which was wise, discriminating, and more than modest; to wide interests in science he united wide interests in the fine arts. Your Astronomer Royal, in the Royal Observatory at Cape Town, will not lightly forget his gift of a great telescope; and the University of Cambridge, the grateful recipient of his munificent endowment of the Isaac Newton Studentships fifteen years ago, and of his no less munificent bequest of manuscripts, early printed books, and objects of art, has done what she can towards perpetuating his memory for future generations by including his name in the list, that is annually recited in solemn service, of her benefactors who have departed this life.

In the early days of our gatherings, when the set of cognate sciences with which we specially are concerned had not yet diverged so widely from one another alike in subject and in method, this inaugurating address was characterised by a brevity that a President can envy and

by a freedom from formality that even the least tolerant audience could find admirable. The lapse of time, perhaps assisted by presidential ambitions which have been veiled under an almost periodic apology for personal shortcomings, has deprived these addresses of their ancient brevity, and has invested them with an air of oracular gravity. The topics vary from year to year, but this variation is due to the predilection of the individual Presidents; the types of address are but few in number. Sometimes, indeed, we have had addresses that cannot be ranged under any comprehensive type. Thus one year we had an account of a particular school of long-sustained consecutive research; another year the President made a constructive (and perhaps defiant) defence of the merits of a group of subjects that were of special interest to himself. But there is one type of address which recurs with iterated frequency; it is constituted by a general account of recent progress in discovery, or by a survey of modern advances in some one or other of the branches of science to which the multiple activities of our Section are devoted. No modern President has attempted a general survey of recent progress in all the branches of our group of sciences; such an attempt will probably be deferred until the Council discovers a President who, endowed with the omniscience of a Whewell, and graced with the tongue of men and of angels, shall once again unify our discussions.

On the basis of this practice, it would have been not unreasonable on my part to have selected some topic from the vast range of pure mathematics, and to have expounded some body of recent investigations. There certainly is no lack of topics; our own day is peculiarly active in many directions. Thus, even if we leave on one side the general progress that has been made in many of the large branches of mathematics during recent years, it is easy to hint at numerous subjects which could occupy the address of a mathematical President. He might, for instance, devote his attention to modern views of continuity, whether of quantity or of space; he might be heterodox or orthodox as to the so-called laws of motion; he might expound his notions as to the nature and properties of analytic functionality; a discussion of the hypotheses upon which a consistent system of geometry can be framed could be made as monumental as his ambition might choose; he could revel in an account of the most recent philosophical analysis of the foundations of mathematics, even of logic itself, in which all axioms must either be proved or be compounded of notions that defy resolution by the human intellect at the present day. Such discussions are bound to be excessively technical unless they are expressed in unmathematical phraseology; when they are so expressed, and in so far as such expression is possible, they become very long and they can be very thin. Moreover, had I chosen any topic of this character, it would have been the merest natural justice to have given early utterance of the sibyllic warning to the uninitiated; I must also have bidden the initiated that, as they come, they should summon all the courage of their souls. So I abstain from making such an experiment upon an unwarned audience; yet it is with reluctance that I have avoided subjects in the range which to me is of peculiar interest.

On the other hand, I must ask your indulgence for not conforming to average practice and expectation. My desire is to mark the present occasion by an address of unspecialised type which, while it is bound to be mainly mathematical in tenor, and while it will contain no new information, may do little more than recall some facts that are known, and will comment briefly upon obvious tendencies. Let me beg you to believe that it is no straining after novelty which has dictated my choice; such an ambition has a hateful facility of being fatal both to the performer and to the purpose. It is the strangeness of our circumstances, both in place and time, that has suggested my subject. With an adventurous audacity that quite overcrows the spirit of any of its past enterprises, the British Association for the Advancement of Science has travelled south of the Equator and, in accepting your hospitality, proposes to traverse much of South Africa. The prophet of old declared that "many shall run to and fro, and knowledge shall be increased"; if the second part of the prophecy is not fulfilled, it will not be for the want of our efforts to fulfil the first part. And if the place and the range of this peripatetic demonstration of our annual corporate activity are unusual, the occasion chosen for this enterprise recalls memories that are fundamental in relation to our subject. It is a modern fashion to observe centenaries. In this section we are in the unusual position of being able to observe three scientific centenaries in one and the same year. Accordingly I propose to refer to these in turn, and to indicate a few of the events filling the intervals between them; but my outline can be of only the most summary character, for the scientific history is a history of three hundred years, and, if searching enough, it could include the tale of nearly all mathematical and astronomical and physical science.

It is exactly three hundred years since Bacon published "The Advancement of Learning." His discourse, alike in matter, in thought, in outlook, was in advance of its time, and it exercised no great influence for the years that immediately followed its appearance; yet that appearance is one of the chief events in the origins of modern natural science. Taking all knowledge to be his province, he surveys the whole of learning: he deals with the discredits that then could attach to it; he expounds both the dignity and the influence of its pursuit; and he analyses all learning, whether of things divine or of things human, into its ordered branches. He points out deficiencies and gaps; not a few of his recommendations of studies, at his day remaining untouched, have since become great branches of human thought and human inquiry. But what concerns us most here is his attitude towards natural philosophy, all the more remarkable because of the state of knowledge of that subject in his day, particularly in England. It is true that Gilbert had published his discovery of terrestrial magnetism some five years earlier, a discovery followed only too soon by his death; but that was the single considerable English achievement in modern science down to Bacon's day.

In order to estimate the significance of Bacon's range of thought let me recite a few facts, as an indication of the extreme tenuity of progressive science in that year (1605). They belong to subsequent years, and may serve to show how restricted were the attainments of the period, and how limited were the means of advance. The telescope and the microscope had not yet been invented. The simple laws of planetary motion were not formulated, for Kepler had them only in the making. Logarithms were yet to be discovered by Napier, and to be calculated by Briggs. Descartes was a boy of nine and Fermat a boy of only four, so that analytical geometry, the middle-life discovery of both of them, was not yet even a dream for either of them. The Italian mathematicians, of whom Cavalieri is the least forgotten, were developing Greek methods of quadrature by a transformed principle of indivisibles; but the infinitesimal calculus was not really in sight, for Newton and Leibnitz were yet unborn. Years were to elapse before, by the ecclesiastical tyranny over thought, Galileo was forced to make a verbal disavowal of his adhesion to the Copernican system of astronomy, of which he was still to be the protagonist in propounding any reasoned proof. Some mathematics could be had, cumbrous arithmetic and algebra, some geometry lumbering after Euclid, and a little trigonometry; but these were mainly the mathematics of the Renaissance, no very great advance upon the translated work of the Greeks and the transmitted work of the Arabs. Even our old friend the binomial theorem, which now is supposed to be the possession of nearly every able schoolboy, remained unknown to professional mathematicians for more than half a century yet to come.

Nor is it merely on the negative side that the times seemed unpropitious for a new departure; the spirit of the age in the positive activities of thought and deed was not more sympathetic. Those were the days when the applications of astronomy had become astrology. Men sought for the elixir of life and pondered over the transmutation of baser metals into gold. Shakespeare not long before had produced his play *As You Like It*, where the strange natural history of the toad which,

> "Ugly and venomous,
> Bears yet a precious jewel in his head."

is made a metaphor to illustrate the sweetening uses of adversity. The stiffened Elizabethan laws against witch-

craft were to be sternly administered for many a year to come. It was an age that was pulsating with life and illuminated by fancy, but the life was the life of strong action and the fancy was the fancy of ideal imagination; men did not lend themselves to sustained and abstract thought concerning the nature of the universe. When we contemplate the spirit that such a state of knowledge might foster towards scientific learning, and when we recall the world into which Bacon's treatise was launched, we can well be surprised at his far-reaching views, and we can marvel at his isolated wisdom.

Let me select a few specimens of his judgments, chosen solely in relation to our own subjects. When he says:

"All true and fruitful natural philosophy hath a double scale or ladder, ascendant and descendant, ascending from experiments to the invention of causes, and descending from causes to the invention of new experiments; therefore I judge it most requisite that these two parts be severally considered and handled"—

he is merely expounding, in what now is rather archaic phrase, the principles of the most ambitious investigations in the natural philosophy of subsequent centuries. When he speaks of

"the operation of the relative and adventive characters of essences, as quantity, similitude, diversity, possibility, and the rest; with this distinction and provision, that they be handled as they have efficacy in nature, and not logically"—

I seem to hear the voice of the applied mathematician warning the pure mathematician off the field. When, after having divided natural philosophy into physic and metaphysic (using these words in particular meanings, and including mathematics in the second of the divisions), he declares

"physic should contemplate that which is inherent in matter, and therefore transitory, and metaphysic that which is abstracted and fixed; . . . physic describeth the causes of things, but the variable or respective causes; and metaphysic the fixed and constant causes"—

there comes before my mind the army of physicists of the present day, who devote themselves unwearyingly to the properties of matter and willingly cast aside elaborate arguments and calculations. When he argues that

"many parts of nature can neither be invented with sufficient subtilty, nor demonstrated with sufficient perspicuity, nor accommodated unto use with sufficient dexterity, without the aid and intervening of the mathematics"—

he might be describing the activity of subsequent generations of philosophers, astronomers, and engineers. And in the last place (for my extracts must have some end), when he expresses the opinion

"that men do not sufficiently understand the excellent use of the pure mathematics, in that they do remedy and cure many defects in the wit and faculties intellectual. For if the wit be too dull, they sharpen it; if too wandering, they fix it; if too inherent in the sense, they abstract it; . . ., in the mathematics, that which is collateral and intervenient is no less worthy than that which is principal and intended"—

I seem to hear an advocate for the inclusion of elementary mathematics in any scheme of general education. At the same time, I wonder what Bacon, who held such an exalted estimate of pure mathematics in its grey dawn, would have said by way of ampler praise of the subject in its fuller day.

It was a splendid vision of inductive science as of other parts of learning; it contained a revelation of the course of progress through the centuries to come. Yet the facts of to-day are vaster than the vision of that long-ago yesterday, and human activity has far outstripped the dreams of Bacon's opulent imagination. He was the harbinger (premature in many respects it must be confessed, but still the harbinger) of a new era. At a time when we are making a new departure in the fulfilment of the purpose of our charter, which requires us "to promote the intercourse of those who cultivate Science in different parts of the British Empire," our Association for the Advancement of Science may pause for a moment to gaze upon the vision revealed three centuries ago in the "Advancement of Learning" by a philosopher whose influence upon the thought of the world is one of the glories of our nation.

I have implied that Bacon's discourse was in advance of its age, so far as England was concerned. Individuals could make their mark in isolated fashion. Thus Harvey, in his hospital work in London, discovered the circulation of the blood; Napier, away on his Scottish estates, invented logarithms; and Horrocks, in the seclusion of a Lancashire curacy, was the first to observe a transit of Venus. But for more than half a century the growth of physical science was mainly due to workers on the continent of Europe. Galileo was making discoveries in the mechanics of solids and fluids, and, specially, he was building on a firm foundation the fabric of the system of astronomy, hazarded nearly a century before by Copernicus; he still was to furnish, by bitter experience, one of the most striking examples in the history of the world that truth is stronger than dogma. Kepler was gradually elucidating the laws of planetary motion, of which such significant use was made later by Newton; and Descartes, by his creation of analytical geometry, was yet to effect such a constructive revolution in mathematics that he might not unfairly be called the founder of modern mathematics. In England the times were out of scientific joint; the political distractions of the Stuart troubles, and the narrow theological bitterness of the Commonwealth, made a poor atmosphere for the progress of scientific learning, which was confined almost to a faithful few. The fidelity of those few, however, had its reward; it was owing to their steady confidence and to their initiative that the Royal Society of London was founded in 1662 by Charles II. At that epoch, science (to quote the words of a picturesque historian) became the fashion of the day. Great Britain began to contribute at least her fitting share to the growing knowledge of Nature; and her scientific activity in the closing part of the seventeenth century was a realisation, wonderful and practical, of a part of Bacon's dream. Undoubtedly the most striking contribution made in that period is Newton's theory of gravitation, as expounded in his "Principia," published in 1687.

That century also saw the discovery of the fluxional calculus by Newton, and of the differential calculus by Leibnitz. These discoveries provided the material for one of the longest and most deadening controversies as to priority in all the long history of those tediously barren occupations; unfortunately they are dear to minds which cannot understand that a discovery should be used, developed, amplified, but should not be a cause of envy, quarrel, or controversy. Let me say, incidentally, that the controversy had a malign influence upon the study of mathematics as pursued in England.

Also, the undulatory theory of light found its first systematic, if incomplete, exposition in the work of Huygens before the century was out. But Newton had an emission theory of his own, and so the undulatory theory of Huygens found no favour in England until rather more than a hundred years later; the researches of Thomas Young established it on a firm foundation.

Having thus noted some part of the stir in scientific life which marked the late years of the seventeenth century, let me pass to the second of our centenaries; it belongs to the name of Edmond Halley. Quite independently of his achievement connected with the year 1705 to which I am about to refer, there are special reasons for honouring Halley's name in this section at our meeting in South Africa. When a young man of twenty-one he left England for St. Helena, and there, in the years 1676–1678, he laid the foundations of stellar astronomy for the Southern Hemisphere; moreover, in the course of his work he there succeeded in securing the first complete observation of a transit of Mercury. After his return to England, the next few years of his life were spent in laying science under a special debt that can hardly be over-appreciated. He placed himself in personal relation with Newton, propounded to him questions and offered information; and it is now a commonplace statement that Halley's questions and suggestions caused Newton to write the "Principia."

More than this, we know that Newton's great treatise saw the light only through Halley's persuasive insistence, through his unwearying diligence in saving Newton all cares and trouble and even pecuniary expense, and through his absolutely self-sacrificing devotion to what he made an unwavering duty at that epoch in his life. Again, he appears to have been the first organiser of a scientific expedition, as distinct from a journey of discovery, towards the Southern Seas; he sailed as far as the fifty-second degree of southern latitude, devised the principle of the sextant in the course of his voyaging, and, as a result of the voyage, he produced a General Chart of the Atlantic Ocean, with special reference to the deviation of the compass. Original, touched with genius, cheery of soul, strenuous in thought and generous by nature, he spent his life in a continuously productive devotion to astronomical science, from boyhood to a span of years far beyond that which satisfied the Psalmist's broodings. I have selected a characteristic incident in his scientific activity, one of the most brilliant (though it cannot be claimed as the most important) of his astronomical achievements; it strikes me as one of the most chivalrously bold acts of convinced science within my knowledge. It is only the story of a comet.

I have just explained, very briefly, Halley's share in the production of Newton's "Principia"; his close concern with it made him the Mahomet of the new dispensation of the astronomical universe, and he was prepared to view all its phenomena in the light of that dispensation. A comet had appeared in 1682—it was still the age when scientific men could think that, by a collision between the earth and a comet, "this most beautiful order of things would be entirely destroyed and reduced to its ancient chaos"; but this fear was taken as a "by-the-bye," which happily interfered with neither observations nor calculations. Observations had duly been made. The data were used to obtain the elements of the orbit, employing Newton's theory as a working hypothesis; and he expresses an incidental regret as to the intrinsic errors of assumed numerical elements and of recorded observations. It then occurred to Halley to calculate similarly the elements of the comet which Kepler and others had seen in 1607, and of which records had been made; the Newtonian theory gave elements in close accord with those belonging to the comet calculated from the latest observations, though a new regret is expressed that the 1607 observations had not been made with more accuracy. On these results he committed himself (being then a man of forty-nine years of age) to a prophecy (which could not be checked for fifty-three years to come) that the comet would return about the end of the year 1758 or the beginning of the next succeeding year; he was willing to leave his conclusion "to be discussed by the care of posterity, after the truth is found out by the event." But not completely content with this stage of his work, he obtained with difficulty a book by Apian, giving an account of a comet seen in 1531 and recording a number of observations. Halley, constant to his faith in the Newtonian hypothesis, used that hypothesis to calculate the elements of the orbit of the Apian comet; once more regretting the uncertainty of the data and discounting a very grievous error committed by Apian himself, Halley concluded that the Apian comet of 1531, and the Kepler comet of 1607, and the observed comet of 1682 were one and the same. He confirmed his prediction as to the date of its return, and he concludes his argument with a blend of confidence and patriotism:—

"Wherefore if according to what we have already said it should return again about the year 1758, candid posterity will not refuse to acknowledge that this was first discovered by an *Englishman.*"

Such was Halley's prediction published in the year 1705. The comet pursued its course, and it was next seen on Christmas Day, 1758. Candid posterity, so far from refusing to acknowledge that the discovery was made by an Englishman, has linked Halley's name with the comet, possibly for all time.

We all now could make announcements on the subject of Halley's comet; their fulfilment could be awaited serenely. No vision or inspiration is needed; calculations and corrections will suffice. The comet was seen in 1835, and it is expected again in 1910. No doubt our astronomers will be ready for it; and the added knowledge of electrical science, in connection particularly with the properties of matter, may enable them to review Bessel's often-discussed conjecture as to an explanation of the emission of a sunward tail. But Halley's announcement was made during what may be called the immaturity of the gravitation theory; the realisation of the prediction did much to strengthen the belief in the theory and to spread its general acceptance; the crown of conviction was attained with the work of Adams and Leverrier in the discovery, propounded by theory and verified by observation, of the planet Neptune. I do not know an apter illustration of Bacon's dictum that has already been quoted, "All true and fruitful natural philosophy hath a double scale, ascending from experiments to the invention of causes, and descending from causes to the invention of new experiments." The double process, when it can be carried out, is one of the most effective agents for the increase of trustworthy knowledge. But until the event justified Halley's prediction, the Cartesian vortex-theory of the universe was not completely replaced by the Newtonian theory; the Cartesian votaries were not at once prepared to obey Halley's jubilant, if stern, injunction to "leave off trifling . . . with their vortices and their absolute plenum . . . and give themselves up to the study of truth."

The century that followed the publication of Halley's prediction shows a world that is steadily engaged in the development of the inductive sciences and their applications. Observational astronomy continued its activity quite steadily, reinforced towards the end of the century by the first of the Herschels. The science of mathematical (or theoretical) astronomy was created in a form that is used to this day; but before this creation could be effected, there had to be a development of mathematics suitable for the purpose. The beginnings were made by the Bernoullis (a family that must be of supreme interest to Dr. Francis Galton in his latest statistical compilations, for it contained no fewer than seven mathematicians of mark, distributed over three generations), but the main achievements are due to Euler, Lagrange, and Laplace. In particular, the infinitesimal calculus in its various branches (including, that is to say, what we call the differential calculus, the integral calculus, and differential equations) received the development that now is familiar to all who have occasion to work in the subject. When this calculus was developed, it was applied to a variety of subjects; the applications, indeed, not merely influenced, but immediately directed, the development of the mathematics. To this period is due the construction of analytical mechanics at the hands of Euler, d'Alembert, Lagrange, and Poisson; but the most significant achievement in this range of thought is the mathematical development of the Newtonian theory of gravitation applied to the whole universe. It was made, in the main, by Lagrange, as regards the wider theory, and by Laplace, as regards the amplitude of detailed application. But it was a century that also saw the obliteration of the ancient doctrines of caloric and phlogiston, through the discoveries of Rumford and Davy of the nature and relations of heat. The modern science of vibrations had its beginnings in the experiments of Chladni, and, as has already been stated, the undulatory theory of light was rehabilitated by the researches of Thomas Young. Strange views as to the physical constitution of the universe then were sent to the limbo of forgotten ignorance by the early discoveries of modern chemistry; and engineering assumed a systematic and scientific activity, the limits of which seem bounded only by the cumulative ingenuity of successive generations. But in thus attempting to summarise the progress of science in that period, I appear to be trespassing upon the domains of other Sections; my steps had better be retraced so as to let us return to our own upper air. If I mention one more fact (and it will be a small one), it is because of its special connection with the work of this Section. As you are aware, the elements of Euclid have long been the standard treatise of elementary geometry in Great Britain; and the Greek methods, in Robert Simson's edition, have been imposed upon candidates in examination after ex-

amination. But Euclid is on the verge of being disestablished; my own University of Cambridge, which has had its full share in maintaining the restriction to Euclid's methods, and which was not uninfluenced by the report of a Committee of this Association upon the subject, will, some six or seven weeks hence, hold its last examination in which those methods are prescriptively required. The disestablishment of Euclid from tyranny over the youthful student on the continent of Europe was effected before the end of the eighteenth century.

But it is time for me to pass on to the third of the centenaries, with which the present year can be associated. Not so fundamental for the initiation of modern science as was the year in which the "Advancement of Learning" was published, not so romantic in the progress of modern science as was the year in which Halley gave his prediction to the world, the year 1805 (turbulent as it was with the strife of European politics) is marked by the silent voices of a couple of scientific records. In that year Laplace published the last progressive instalment of his great treatise on Celestial Mechanics, the portion that still remained for the future being solely of an historical character; the great number of astronomical phenomena which he had been able to explain by his mathematical presentation of the consequences of the Newtonian theory would, by themselves, have been sufficient to give confidence in the validity of that theory. In that year also Monge published his treatise, classical and still to be read by all students of the subject, "The Application of Algebra to Geometry"; it is the starting point of modern synthetic geometry, which has marched in ample development since his day. These are but landmarks in the history of mathematical science, one of them indicating the completed attainment of a tremendous task, the other of them initiating a new departure; both of them have their significance in the progress of their respective sciences.

When we contemplate the activity and the achievements of the century that has elapsed since the stages which have just been mentioned were attained in mathematical science, the amount, the variety, the progressive diligence, are little less than bewildering. It is not merely the vast development of all the sciences that calls for remark; no less striking is their detailed development. Each branch of science now has an enormous array of workers, a development rendered more easily possible by the growing increase in the number of professional posts; and through the influence of these workers and their labours there is an ever-increasing body of scientific facts. Yet an aggregate of facts is not an explanatory theory any more necessarily than a pile of carefully fashioned stones is a cathedral; and the genius of a Kepler and a Newton is just as absolutely needed to evolve the comprehending theory as the genius of great architects was needed for the Gothic cathedrals of France and of England. Not infrequently it is difficult to make out what is the main line of progress in any one subject, let alone in a group of subjects; and though illumination comes from striking results that appeal, not merely to the professional workers, but also to unprofessional observers, this illumination is the exception rather than the rule. We can allow, and we should continue to allow, freedom of initiative in all directions. That freedom sometimes means isolation, and its undue exercise can lead to narrowness of view. In spite of the complex ramification of the sciences which it has fostered, it is a safer and a wiser spirit than that of uncongenial compulsion, which can be as dogmatic in matters scientific as it can be in matters theological. Owing to the varieties of mind, whether in individuals or in races, the progress of thought and the growth of knowledge are not ultimately governed by the wishes of any individual or the prejudices of any section of individuals. Here, a school of growing thought may be ignored; there, it may be denounced as of no importance; somewhere else, it may be politely persecuted out of possible existence. But the here, and the there, and the somewhere else do not make up the universe of human activity; and that school, like Galileo's earth in defiance of all dogmatic authority, still will move.

This complete freedom in the development of scientific thought, when the thought is applied to natural phenomena, is all the more necessary because of the ways of Nature. Physical nature cares nothing for theories, nothing for calculations, nothing for difficulties, whatever their source; she will only give facts in answer to our questions, without reasons and without explanations; we may explain as we please and evolve laws as we like, without her help or her hindrance. If from our explanations and our laws we proceed to prediction, and if the event justifies the prediction through agreement with recorded fact, well and good; so far we have a working hypothesis. The significance of working hypotheses, in respect of their validity and their relation to causes, is a well known battle-ground of dispute between different schools of philosophers; it need not detain us here and now. On the other hand, when we proceed from our explanations and our laws to a prediction, and the prediction in the end does not agree with the fact to be recorded, it is the prediction that has to give way. But the old facts remain and the new fact is added to them; and so facts grow until some working law can be extracted from them. This accumulation of facts is only one process in the solution of the universe; when the compelling genius is not at hand to transform knowledge into wisdom, useful work can still be done upon them by the construction of organised accounts which shall give a systematic exposition of the results, and shall place them as far as may be in relative significance.

Let me pass from these generalities, which have been suggested to my mind by the consideration of some of the scientific changes that have taken place during the last hundred years, and let me refer briefly to some of the changes and advances which appear to me to be most characteristic of that period. It is not that I am concerned with a selection of the most important researches of the period. Estimates of relative importance are often little more than half-concealed expressions of individual preferences or personal enthusiasms; and though each enthusiastic worker, if quite frank in expressing his opinion, would declare his own subject to be of supreme importance, he would agree to a compromise that the divergence between the different subjects is now so wide as to have destroyed any common measure of comparison. My concern is rather with changes, and with tendencies where these can be discerned.

The growth of astronomy has already occupied so large a share of my remarks that few more words can be spared here. Not less, but more, remarkable than the preceding centuries in the actual exploration of the heavens, which has been facilitated so much by the improvements in instruments and is reinforced to such effect by the cooperation of an ever-growing band of American astronomers, it has seen a new astronomy occupy regions undreamt of in the older days. New methods have supplemented the old; spectroscopy has developed a science of physics within astronomy; and the unastronomical brain reels at the contents of the photographic chart of the heavens which is now being constructed by international cooperation and will, when completed, attempt to map ten million stars (more or less) for the human eye.

Nor has the progress of physics, alike on the mathematical side and the experimental side, been less remarkable or more restricted than that of astronomy. The elaborate and occasionally fantastic theories of the eighteenth century, in such subjects as light, heat, even as to matter itself, were rejected in favour of simpler and more comprehensive theories. There was one stage when it seemed as if the mathematical physicists were gradually overtaking the experimental physicists; but the discoveries in electricity begun by Faraday left the mathematicians far behind. Much has been done towards the old duty, ever insistent, of explaining new phenomena; and the names of Maxwell, Weber, Neumann, and Hertz need only to be mentioned in order to suggest the progress that has been made in one subject alone. We need not hesitate to let our thoughts couple, with the great physicists of the century, the leaders of that brilliant band of workers upon the properties of matter who carry us on from wonder to wonder with the passage of each successive year.

Further, it has been an age when technical applications have marched at a marvellous pace. So great has been their growth that we are apt to forget their comparative youth; yet it was only the middle of the century which

saw the awakening from what now might be regarded as the dark ages. Nor is the field of possible application nearing exhaustion; on the contrary, it seems to be increasing by reason of new discoveries in pure science that yet will find some beneficent outcome in practice. Invisible rays and wireless telegraphy may be cited as instances that are occupying present activities, not to speak of radium, the unfolding of the future of which is watched by eager minds.

One gap, indeed, in this subject strikes me. There are great histories of mathematics and great histories of astronomy; I can find no history of physics on the grand scale. Some serviceable manuals there are, as well as monographs on particular topics; what seems to me to be lacking is some comprehensive and comparative survey of the whole range. The history of any of the natural sciences, like the history of human activity, is not merely an encyclopædic record of past facts; it reveals both the spirit and the wealth which the past has bequeathed to the present, and which, in due course, the present will influence before transmission to the future. Perhaps all our physicists are too busy to spare the labour needed for the production of a comprehensive history; yet I cannot help thinking that such a contribution to the subject would be of great value, not to physicists alone.

But, as you hear me thus referring to astronomy and to physics, some of you may think of the old Roman proverb which bade the cobbler not to look above his last; so I take the opportunity of referring very briefly to my own subject. One of the features of the century has been the continued development of mathematics. As a means of calculation the subject was developed as widely during the earlier portion of the century as during the preceding century; it soon began to show signs of emergence as an independent science, and the later part of the century has witnessed the emancipation of pure mathematics. It was pointed out, in connection with the growth of theoretical astronomy, that mathematics developed in the direction of its application to that subject. When the wonderful school of French physicists, composed of Monge, Carnot, Fourier, Poisson, Poinsot, Ampère, and Fresnel (to mention only some names), together with Gauss, Kirchhoff, and von Helmholtz in Germany, and Ivory, Green, Stokes, Maxwell, and others in England, applied their mathematics to various branches of physics, for the most part its development was that of an ancillary subject. The result is the superb body of knowledge that may be summarised under the title of "mathematical physics"; but the final interest is the interest of physics, though the construction has been the service of mathematics. Moreover, this tendency was deliberate, and was avowed in no uncertain tone. Thus Fourier could praise the utility of mathematics by declaring that "there was no language more universal or simpler, more free from errors or obscurity, more worthy of expressing the unchanging relations of natural entities"; in a burst of enthusiasm he declares that, from the point of view he had indicated, "mathematical analysis is as wide as Nature herself," and "it increases and grows incessantly stronger amid all the changes and errors of the human mind." Mathematicians might almost blush with conscious pleasure at such a laudation of their subject from such a quarter, though it errs both by excess and defect; but the exultation of spirit need not last long. The same authority, when officially expounding to the French Academy the work of Jacobi and of Abel upon elliptic functions, expressed his chilling opinion (it had nothing to do with the case) that "the questions of natural philosophy, which have the mathematical study of all important phenomena for their aim, are also a worthy and principal subject for the meditations of geometers. It is to be desired that those persons who are best fitted to improve the science of calculation should direct their labours to these important applications." Abel was soon to pass beyond the range of admonition; but Jacobi, in a private letter to Legendre, protested that the scope of the science was not to be limited to the explanation of natural phenomena. I have not quoted these extracts by way of even hint of reproach against the author of such a wonderful creation as Fourier's analytical theory of heat; his estimate could have been justified on a merely historical review of the circumstances of his own time and of past times; and I am not sure that his estimate has not its exponents at the present day. But all history shows that new discoveries and new methods can spread to issues wider than those of their origins, and that it is almost a duty of human intelligence to recognise this possibility in the domain of progressive studies. The fact is that mathematical physics and pure mathematics have given much to each other in the past and will give much to each other in the future; in doing so, they will take harmonised action in furthering the progress of knowledge. But neither science must pretend to absorb the activity of the other. It is almost an irony of circumstance that a theorem, initiated by Fourier in the treatise just mentioned, has given rise to a vast amount of discussion and attention, which, while of supreme value in the development of one branch of pure mathematics, have hitherto offered little, if anything, by way of added explanation of natural phenomena.

The century that has gone has witnessed a wonderful development of pure mathematics. The bead-roll of names in that science—Gauss; Abel, Jacobi; Cauchy, Riemann, Weierstrass, Hermite; Cayley, Sylvester; Lobatchewsky, Lie—will on only the merest recollection of the work with which their names are associated show that an age has been reached where the development of human thought is deemed as worthy a scientific occupation of the human mind as the most profound study of the phenomena of the material universe.

The last feature of the century that will be mentioned has been the increase in the number of subjects, apparently dissimilar from one another, which are now being made to use mathematics to some extent. Perhaps the most surprising is the application of mathematics to the domain of pure thought; this was effected by George Boole in his treatise "Laws of Thought," published in 1854; and though the developments have passed considerably beyond Boole's researches, his work is one of those classics that mark a new departure. Political economy, on the initiative of Cournot and Jevons, has begun to employ symbols and to develop the graphical methods; but, there, the present use seems to be one of suggestive record and expression, rather than of positive construction. Chemistry, in a modern spirit, is stretching out into mathematical theories; Willard Gibbs, in his memoir on the equilibrium of chemical systems, has led the way; and, though his way is a path which chemists find strewn with the thorns of analysis, his work has rendered, incidentally, a real service in coordinating experimental results belonging to physics and to chemistry. A new and generalised theory of statistics is being constructed; and a school has grown up which is applying them to biological phenomena. Its activity, however, has not yet met with the sympathetic goodwill of all the pure biologists; and those who remember the quality of the discussion that took place last year at Cambridge between the biometricians and some of the biologists will agree that, if the new school should languish, it will not be for want of the tonic of criticism.

If I have dealt with the past history of some of the sciences with which our Section is concerned, and have chosen particular epochs in that history with the aim of concentrating your attention upon them, you will hardly expect me to plunge into the future. Being neither a prophet nor the son of a prophet, not being possessed of the knowledge which enabled Halley to don the prophet's mantle with confidence, I shall venture upon no prophecy even so cautious as Bacon's—"As for the mixed mathematics I may only make this prediction, that there cannot fail to be more kinds of them as Nature grows further disclosed"—a declaration that is sage enough, though a trifle lacking in precision. Prophecy, unless based upon confident knowledge, has passed out of vogue, except perhaps in controversial politics; even in that domain, it is helpless to secure its own fulfilment. Let me rather exercise the privilege of one who is not entirely unfamiliar with the practice of geometry, and let me draw the proverbial line before indulgence in prophetic estimates. The names that have flitted through my remarks, the discoveries and the places associated with those names, definitely indicate that, notwithstanding all appearance of

divergence and in spite of scattered isolation, the sum of human knowledge, which is an inheritance common to us all, grows silently, sometimes slowly, yet (as we hope) safely and surely, through the ages. You who are in South Africa have made an honourable and an honoured contribution to that growing knowledge, conspicuously in your astronomy and through a brilliant succession of astronomers. Here, not as an individual but as a representative officer of our brotherhood in the British Association, I can offer you no better wish than that you may produce some men of genius and a multitude of able workers who, by their researches in our sciences, may add to the fame of your country and will contribute to the intellectual progress of the world.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY G. T. BEILBY, PRESIDENT OF THE SECTION.

IN scanning the list of the elements with which we are thoughtfully supplied every year by the International Committee on Atomic Weights, the direction in which our thoughts are led will depend on the particular aspect of chemical study which happens to interest us at the time. Putting from our minds on the present occasion the attractive speculations on atomic constitution and disintegration with which we have all become at least superficially familiar during the past few years, let us try to scan this list from the point of view of the "plain man" rather than from that of the expert chemist. Even a rudimentary knowledge will be sufficient to enable our "plain man" to divide the elements broadly into two groups—the actually useful and the doubtfully useful or useless. Without going into detail we may take it that about two-thirds would be admitted into the first group, and one-third into the second. It must, I think, be regarded as a very remarkable fact that of the eighty elements which have had the intrinsic stability to enable them to survive the prodigious forces which must have been concerned in the evolution of the physical universe, so large a proportion are endowed with characteristic properties which could ill have been spared either from the laboratories of Nature or from those of the Arts and Sciences. Even if one-third of the elements are to be regarded as waste products or failures, there is here no counterpart to the reckless prodigality of Nature in the processes of organic evolution.

If we exclude those elements which participate directly and indirectly in the structure and functions of the organic world, there are two elements which stand out conspicuously because of the supreme influence they have exercised over the trend of human effort and ambition. I refer, of course, to the metals gold and iron.

From the early beginnings of civilisation gold has been highly prized and eagerly sought after. Human life has been freely sacrificed in its acquirement from natural sources, as well as in its forcible seizure from those who already possessed it. The "Age of Gold" was not necessarily "The Golden Age," for the noble metal in its unique and barbaric splendour has symbolised much that has been unworthy in national and individual aims and ideals.

We have accustomed ourselves to think of the present as the Age of Iron, as indeed it is, for we see in the dull, grey metal the plastic medium out of which the engineer has modelled the machines and structures which play so large a part in the active life of to-day. Had iron not been at once plentiful and cheap, had it not brought into the hands of the engineer and artificer its marvellous qualities of hardness and softness, of rigidity and toughness, and to the electrician its mysterious and unique magnetic qualities, it is not difficult to conceive that man's control over the forces of Nature might have been delayed for centuries, or perhaps for ages. For iron has been man's chief material instrument in the conquest of Nature; without it the energy alike of the waterfall and of the coalfield would have remained uncontrolled and unused. In this conquest of the resources of Nature for the service of man are we not entitled to say that the intellectual and social gains have equalled, if they have not exceeded, in value the purely material gains; and may we not then regard iron as the symbol of a beneficent conquest of Nature?

With the advent of the Industrial Age gold was destined to take a new place in the world's history as the great medium of exchange, the great promoter of industry and commerce. While individual gain still remained the propelling power towards its discovery and acquisition, every fresh discovery led directly or indirectly to the freer interchange of the products of industry, and thus reacted favourably on the industrial and social conditions of the time.

So long as the chief supplies of gold were obtained from alluvial deposits by the simple process of washing, the winning of gold almost necessarily continued to be pursued by individuals, or by small groups of workers, who were mainly attracted by the highly speculative nature of the occupation. These workers endured the greatest hardships and ran the most serious personal risks, drawn on from day to day by the hope that some special stroke of good fortune would be theirs. This condition prevailed also in fields in which the reef gold occurred near the surface, where it was easily accessible without costly mining appliances, and where the precious metal was loosely associated with a weathered matrix. These free-milling ores could be readily handled by crushing and amalgamation with mercury, so that here also no elaborate organisation and no great expenditure of capital were necessary. A third stage was reached when the more easily worked deposits above the water-line had been worked out. Not only were more costly appliances and more elaborately organised efforts required to bring the ore to the surface, but the ore when obtained contained less of its gold in the easily recovered, and more in the refractory or combined form. The problem of recovery had now to be attacked by improved mechanical and chemical methods. The sulphides or tellurides with which the gold was associated or combined had to be reduced to a state of minute subdivision by more perfect stamping or grinding, and elaborate precautions were necessary to ensure metallic contact between the particles of gold and the solvent mercury. In many cases the amalgamation process failed to extract more than a very moderate proportion of the gold, and the quartz sand or "tailings" which still contained the remainder found its way into creeks and rivers or remained in heaps on the ground around the batteries. In neighbourhoods where fuel was available a preliminary roasting of the ore was resorted to, to oxidise or volatilise the baser metals and set free the gold; or the sulphides, tellurides, &c., were concentrated by washing, and the concentrates were taken to smelting or chlorinating works in some favourable situation where the more elaborate metallurgical methods could be economically applied. Many efforts were also made to apply the solvent action of chlorine directly to the unconcentrated unroasted ores; but unfortunately chlorine is an excellent solvent for other substances besides gold, and in practice it was found that its solvent energy was mainly exercised on the base metals and metalloids, and on the materials of which the apparatus itself was constructed.

This to the best of my knowledge is a correct, if rather sketchy, description of the state of matters in 1889 when the use of a dilute solution of cyanide of potassium was first seriously proposed for the extraction of gold from its ores. Those of us who can recall the time will remember that the proposal was far from favourably regarded from a chemical point of view. The cost of the reagent, its extremely poisonous nature, the instability of its solutions, its slow action—such were the difficulties that naturally presented themselves to our minds. And, even granting that these difficulties might be overcome, there still remained the serious problem of how to recover the gold in metallic form from the extremely dilute solutions of the cyanide of gold and potassium. How each and all of these difficulties have been swept aside, how within little more than a decade this method of gold extraction has spread over the gold-producing countries of the world, now absorbing and now replacing the older processes, but ever carrying all before it—all this is already a twice-told tale which I should feel hardly justified in

alluding to were it not for the fact that we are to-day meeting on the Rand where the infant process made its *début* nearly fourteen years ago. The Rand to-day is the richest of the world's goldfields, not only in its present capacity, but in its potentialities for the future; twenty years ago its wonderful possibilities were quite unsuspected even by experts.

It is not for me to describe in detail how the change has been accomplished; this task will, we know, be far better accomplished by representative chemists who are now actively engaged in the work. But for the chemists of the British Association it is a fact of great significance that they are here in the presence of the most truly industrial development of gold production which the world has yet seen; a development moreover that is founded on a purely chemical process which for its continuance requires, not only skilled chemists to superintend its operation, but equally skilled chemists to supply the reagent on which the industry depends.

In 1889 the world's consumption of cyanide of potassium did not exceed fifty tons per annum. This was produced by melting ferrocyanide with carbonate of potassium, the clear fused cyanide so obtained being decanted from the carbide of iron which had separated. The resulting salt was a mixture of cyanide, cyanate, and carbonate which was sometimes called cyanide of potassium for the hardly sufficient reason that it contained 30 per cent. of that salt. When the demand for gold extraction arose, it was at first entirely met by this process, the requisite ferrocyanide being obtained by the old fusion process from the nitrogen of horns, leather, &c. In 1891 the first successful process for the synthetic production of cyanide without the intervention of ferrocyanide was perfected, and the increasing demand from the gold mines was largely met by its use. At present the entire consumption of cyanide is not much short of 10,000 tons a year, of which the Transvaal goldfield consumes about one-third. Large cyanide works exist in Great Britain, Germany, France, and America, so that a steady and sure supply of the reagent has been amply provided. In 1894 the price of cyanide in the Transvaal was 2*s.* per pound; to-day it is one-third of that, or 8*d.* During the prevalence of the high prices of earlier years the manufacture was a highly speculative one, and new processes appeared and disappeared with surprising suddenness, the disappearance being generally marked by the simultaneous vanishing of large sums of money. To-day the manufacture is entirely carried out in large works scientifically organised and supervised, and, both industrially and commercially, the speculative element has been eliminated.

Chemistry has so often been called on to play the part of the humble and unrecognised handmaiden to the industrial arts that we may perhaps be pardoned if in this case we direct public attention to our Cinderella as she shines in her rightful position as the genius of industrial initiation and direction.

To this essentially chemical development of metallurgy we owe it that in a community the age of which can only be counted by decades we find ourselves surrounded by chemists of high scientific skill and attainments who have already organised for their mutual aid and scientific enlightenment "The Johannesburg Society of Chemistry, Metallurgy, and Mining," the published proceedings of which amply testify to the atmosphere of intellectual vigour in which the work of this great industry is carried on.

It appears, then, that while gold still maintains its position of influence in the affairs of men, the nature of that influence has undergone an important change. Not only has its widespread use as the chief medium of exchange exercised far-reaching effects on the commerce of the world, but the vastly increased demand for this purpose has in its turn altered the methods of production. These methods have become more highly organised and scientific, and gold production is now fairly established as a progressive industry in which scope is found for the best chemical and engineering skill and talent.

The experience of more highly evolved industries in the older countries has shown that the truly scientific organisation of industry includes in its scope a full and just consideration for the social and intellectual needs of its workers from highest to lowest. It augurs well, therefore, for the future of the gold industry, from the humane and social points of view, that its control should be more and more under the influence of men of scientific spirit and intellectual culture who we may feel assured will not forget the best traditions of their class.

The application of science to industry requires on the part of the pioneers and organisers keen and persistent concentration on certain well-defined aims. Any wavering in these aims or any relaxation of this concentration may lead to failure or to only a qualified success. This necessary but narrow concentration may be a danger to the intellectual development of the worker, who may thereby readily fall into a groove and so may become even less efficient in his own particular work. It certainly requires some mental strength to hold fast to the well-defined practical aim while allowing to the attention occasional intervals of liberty to browse over the wide and pleasant fields of science. But I am certain that the acquirement of this double power is well worth an effort. The mental stimulus, as well as the new experiences garnered during the excursion, will sooner or later react favourably on the practical problems, while the earnest wrestling with these problems may develop powers and intuitions which will lend their own charm to the wider problems of science.

Gold and Science.

If we re-peruse the table of the elements, not now in our capacity as "plain men" but as chemists, we shall certainly not select gold as of supreme interest chemically. Its position as chief among the noble metals, its patent of nobility, is based on its aloofness from common associations or attachments. Unlike the element nitrogen, it is mainly for itself and little if at all for its compounds, that gold is interesting. In it we can at our leisure study the *metal* rather than the *element*. Its colour and transparence, its softness and its hardness, the density as well as the extreme tenuity of some of its forms—such were the qualities which recommended it to Faraday when he desired to study the action of material particles on light. I should like to repeat to you in his own words the reasons he gave for this choice: "Because of its comparative opacity among bodies, and yet possession of a real transparency; because of its development of colour both in the reflected and transmitted rays; because of the state of tenuity and division which it permitted with the preservation of its integrity as a metallic body; because of its supposed simplicity of character; and because known phenomena appeared to indicate that a mere variation in the size of its particles gave rise to a variety of resultant colours. Besides the waves of light are so large compared to the dimensions of the particles of gold which in various conditions can be subjected to a ray, that it seemed probable that the particles might come into effective relations to the much smaller vibrations of the other particles."

I may remind you that Faraday came to the conclusion that the variety in the colours presented by gold under various conditions is due to the size of its particles and their state of aggregation. Ruby glass or ruby solutions he proved are not true solutions, nor are they molecular diffusions of gold, but they contain the metal in aggregates sufficiently large to give a sensible reflection under an incident beam of light. Through the kindness of Sir Henry Roscoe I am able to exhibit to you some of the original ruby gold preparations obtained during this research, which were afterwards presented to him by Faraday at the Royal Institution some years before his death.

By means of refined and ingenious optical methods Zsigmondy and Siedentopf have succeeded in making these ultra-microscopic particles visible in the microscope as diffraction discs; they have, further, counted the number of particles per unit area, and have from the intensity of their reflection calculated their size. In ruby glass the size of the particles in different specimens was found to vary from 4 to 791 millionths of a millimetre. No relation was found to hold between the colour of the particles and their absolute size. This conclusion is in direct contradiction of Faraday's belief already referred to. Mr. J. Maxwell Garnett has recently shown that the colour

of metallic glasses and films is determined, not only by the absolute size of the metal particles, but also by the proportion of the total volume they occupy in the medium in which they are diffused. The results of Mr. Garnett's calculations are in close agreement with a number of the observations on the colour and microstructure of thin metal films which I had already recorded, and they appear to me to supply the explanation of much that had appeared puzzling before. My own observations lead me to think that the actual microscopic particles which are to be seen, and the larger of which can also be measured, in films and solutions or suspensions, do not in any way represent the ultimate units of structure which are required by Mr. Garnett's theory, but that these particles are aggregates of smaller units built up in more or less open formation.

That a relatively opaque substance like gold may be so attenuated that when disseminated in open formation it becomes transparent is contrary to all our associations with the same operation when performed on transparent substances like glass or crystalline salts. The familiar experiment of crushing a transparent crystal into a perfectly opaque powder would not prepare us for the effect of minute subdivision on the transparence of metals. At first it might be supposed that this difference is due to the very rough and incomplete subdivision of the crystal by crushing; but this is not the case, for the perfectly transparent oxide of magnesium may be obtained in a state of attenuation comparable with that of the gold, by allowing the smoke from burning magnesium to deposit on a glass plate. The film of oxide obtained in this way is found to be built up of particles quite as minute as those of which the gold films are composed, yet the opacity of the oxide film is relatively much greater. The minute particles of the dielectric, magnesium oxide, scatter and dissipate the light waves by repeated reflection and refraction, while the similar particles of the metallic conductor, gold, act as electrical resonators which pass on some of the light waves while reflecting others. Specimens of films of gold and silver and of magnesium oxide are exhibited on the table and on the lantern screen. When the metallic particles are in this state of open formation and relative transparence, it was found that the electrical conductivity of the films had completely disappeared. Films of this description were found to have a resistance of more than 1,000,000 megohms as compared with only six ohms in the metallic reflecting condition.

Molecules in the Solid State.

My examination of gold films and surfaces has revealed the fact that during polishing the disturbed surface film behaves exactly like a liquid under the influence of surface tension. At temperatures far below the melting point molecular movement takes place under mechanical disturbance, and the molecules tend to heap up in minute mounds or flattened droplets. These minute mounds are often so shallow that they can only be detected when the surface is illuminated by an intense, obliquely incident beam of light. I have estimated that these minute mounds or spicules can be seen in this way in films which are not more than five to ten micro-millimetres in thickness. A film of this attenuation may contain so few as ten to twenty molecules in its thickness.

When moderately thin films of gold are supported on glass and heated at a temperature of 400°–500°, they become translucent, and the forms assumed under the influence of surface tension can be readily seen by transmitted light. It was in this way that the beautiful but puzzling spicular appearance by obliquely reflected light was first explained as due to the granulation of the surface under the influence of surface tension. Photomicrographs of these films are exhibited.

Turning now to the mechanical properties of metals, we find that gold has proved itself of great value in the investigation of some of these. It has long been recognised as the most malleable and ductile of the metals, whilst its chemical indifference tends to preserve it in a state of metallic purity throughout any prolonged series of operations.

The artificers in gold must very early have learned that its malleability and ductility are not qualities which indefinitely survive the operations of hammering and wire-drawing. A piece of soft gold beaten into a thin plate does not remain equally soft throughout the process, but spreads with increasing difficulty under the hammer. If carelessly beaten it may even develop cracks round its edges. We may assume that the artificers in gold very soon discovered that by heating, the hardened metal might be restored to its former condition of softness.

In connection with the study of the micro-metallurgy of iron and steel during recent years it has been recognised that heat annealing is, as a rule, associated with the growth and development of crystalline grains, and Prof. Ewing and Mr. Rosenhain have shown that overstrain is often if not invariably associated with the deformation of these crystalline grains by slips occurring along one or more cleavage planes. This hypothesis, though well supported up to a point by microscopic observations on a variety of metals, offers no explanation of the natural arrest of malleability or ductility which occurs when the overstrain has reached a point at which the crystalline grains are still, to all appearance, only slightly deformed. At this stage there is no obvious reason why the slipping of the crystalline lamellæ should not continue under the stresses which have initiated it. But far from this being the case, a relatively great increase of stress produces little or no further yielding until the breaking point is reached and rupture takes place.

The study of the surface effects of polishing, already referred to, had shown that the thin surface film retained no trace of crystalline structure; while it also gave the clearest indications that the metal had passed through a liquid condition before settling into the forms prescribed by surface tension. From this it was argued that the conditions which prevail at the outer surface might equally prevail at all inner surfaces where movement had occurred, so that every slip of one crystalline lamella over another would cause a thin film of the metal to pass through the liquid phase to a new and non-crystalline condition. By observations on the effects of beating pure gold foil, it was found that the metal reached its hardest and least plastic condition only when all outward traces of crystalline structure had disappeared. It was also ascertained that this complete destruction of the crystalline lamellæ and units could only be accomplished in the layers near the surface, for the hardened substance produced by the flowing under the hammer appears to encase and protect the crystalline units after they become broken down to a certain size. By carefully etching the surface in stages by means of chlorine water or cold aqua regia, the successive layers below the surface were disclosed. The surface itself was vitreous; beneath this was a layer of minute granules, and lower still the distorted and broken-up remains of crystalline lamellæ and grains were embedded in a vitreous and granular matrix. The vitreous-looking surface layer represents the final stage in the passage from soft to hard, from crystalline to amorphous. By heating the beaten foil, its softness was restored; and on etching the annealed metal it was found that the crystalline structure also was fully restored. Photomicrographs showing these appearances are exhibited. These microscopic observations were fully confirmed by finding well-marked thermo-electrical and electro-chemical distinctions between the two forms of metal, the hard and soft or the amorphous and the crystalline. The determination of a definite transition temperature at which the amorphous metal passes into the crystalline metal further confirms the phase view of hardening by overstrain and softening by annealing.

It was subsequently proved that *the property of passing from crystalline to amorphous by mechanical flow, and from amorphous to crystalline by heat at a definite transition temperature, is a general one which is possessed by all crystalline solids which do not decompose at or below their transition temperature.* The significance of this fact I venture to think entitles it to more than a passing reference. It appears to me to mean that the transition from amorphous to crystalline is entitled to take its place with the other great changes of state, solid to liquid, liquid to gas, for like these it marks a change in the molecular activity which occurs when a certain temperature is reached. It is entitled to take this place because there is every indication that the change is as general in its nature as the other changes of state. Compare it, for instance, with the allotropic changes with which chemists have been

familiar. These are for the most part changes which are special to particular elements or compounds, and are usually classed with the chemical properties by which the substances may be distinguished from each other. Very different is the amorphous crystalline change, for although in particular cases it may have been observed and associated with allotropic changes, yet the causes of its occurrence are more deeply founded in the relations between the molecules and the heat energy by which their manifold properties are successively unfolded as temperature is raised from the absolute zero. At this transition point we find ourselves face to face with the first stirrings of a specific directive force by which the blind cohesion of the molecules is ordered and directed to the building up of the most perfect geometric forms. It is hardly possible any longer to regard the stability of a crystal as static and inert, and independent of temperature; rather must its structure and symmetry be taken as the outward manifestation of a dynamic equilibrium between the primitive cohesion and the kinetic energy imparted by heat. Even before the discovery of a definite temperature of transition from the amorphous to the crystalline phase we had in our hands the proofs that in certain cases the crystalline state can be a state of dynamic, rather than of static equilibrium. The transition of sulphur from the rhombic to the prismatic form supplies an example of crystalline stability which persists only between certain narrow limits of temperature. Within these limits the crystal is a "living crystal" if one may borrow an analogy from the organic world. It can still grow, and it will under proper conditions repair any damage it may receive.

The passage of the same substance through several crystalline phases, each only stable over a limited range of temperature, strongly supports the general conclusion drawn from the existence of a stability temperature between the amorphous and crystalline phases, namely, that the crystalline arrangement of the molecules requires for its active existence the particular kind or rate of vibration corresponding with a certain range of temperature. Below this point the crystal may become to all appearance a mere pseudomorph with no powers of active growth or repair. But these powers are not extinct—they are only in abeyance ready to be called forth under the energising influence of heat. This temporary abeyance of the more active properties of matter is strikingly illustrated by the early observations of Sir James Dewar at the boiling point of liquid air, and more recently at that of liquid hydrogen. At the latter temperature even chemical affinity becomes latent. In metals it was found that the changes in their physical properties brought about by these low temperatures are not permanent, but only persist so long as the low temperature is maintained. During the past year Mr. R. A. Hadfield has supplemented these earlier results by making a very complete series of observations on the effect of cooling on the mechanical properties of iron and its alloys. The tenacity and hardness of the pure metal and its alloys at the ordinary temperature and at -182° have been compared, and it has been found that these qualities are invariably enhanced at the lower temperature, but that they return exactly to their former value at the ordinary temperature. By the mere abstraction of heat between the temperatures of 18° and -182° the tensile strength of pure metals is raised 50 to 100 per cent. In pure iron the increase is from 23 tons per square inch at 18° C. to 52 tons at -182°; in gold from 15·1 tons to 22·4 tons; and in copper from 19·5 tons to 26·4. This increase is not, I think, due to the closer approximation of the molecules, for the coefficient of expansion of most metals below 0° is extremely small. Neither is it due to permanent changes of molecular arrangement or aggregation, for Mr. Hadfield has obtained a perfectly smooth and regular cooling curve for iron between 18° and -182°, and there appears to be no indication of the existence of any critical point between these temperatures. Further, the complete restoration of the original tenacity on the return to the higher temperature shows that no permanent or irreversible change has occurred during cooling. Everything therefore indicates that the increase of tenacity which occurs degree by degree as heat is removed is due to the reduction of the repulsive force of molecular vibration, so that the primary cohesive force can assert itself more and more completely as the absolute zero is approached.

The metals experimented with by Mr. Hadfield were all in the annealed or crystalline condition, so that the molecules must have exerted their mutual attractions along the directed axes proper to this state. It is to be expected that similar experiments with the metals in the amorphous state may throw light on the question whether and to what extent the crystalline state depends on a dynamic equilibrium between the forces of cohesion and repulsion, or whether a directed cohesion exists fully developed in the molecules at the absolute zero.[1]

The phenomena of the solid state throw an interesting light on the interplay of the two great forces, the primative or blind cohesion which holds undisputed sway at the absolute zero, and the repulsion due to the molecular vibrations which is developed by heat. This interplay we know continues through the states which succeed each other as the temperature is raised, until a point is reached at which the molecular repulsions so far outweigh the cohesive force that the substance behaves like a perfect gas. The problems of molecular constitution are more likely to be elucidated by a study of the successive states between the absolute zero and the vaporising temperature than at the upper ranges where the gaseous state alone prevails. The simplicity of the laws which govern the physical behaviour of a perfect gas is very attractive, but we must not forget that this simplicity is only possible because repulsion has so nearly overcome cohesion that the latter may be practically ignored. The attractiveness of this simplicity should not blind us to the fact that it is in the middle region, where the opposing forces are more nearly equal, that the most interesting and illuminating phenomena are likely to abound. The application of the gas laws to the phenomena of solution and osmosis appears to be one of those cases in which an attractive appearance of simplicity in the apparent relations may prove very misleading.

Before passing from the specially metallic qualities of gold I will only remind you of the important part it has played in the researches on the diffusion of metals by the late Sir William Roberts-Austen, and in those of Mr. Haycock and Mr. Neville on the freezing points of solutions of gold in tin, which led to the recognition of the monatomic nature of the molecules of metals.

Molecules in Solution.

It has occurred to me that the practice of the cyanide process of gold extraction presents us with several new and interesting aspects of the problems of solution. As you are aware, the gold is first obtained from the ore in the form of a very dilute solution of cyanide of gold and potassium from which the metal has to be separated, either by passing it through boxes filled with zinc shavings, or by electrolysis in large cells.

The solution as it leaves the cyanide-vats may contain gold equal to 100 grains or more per ton, and as it leaves the precipitating-boxes it may contain as little as 1 or 2 grains and as much as 20 grains. In the treatment of slimes much larger volumes of solution have to be dealt with, and in this case solutions containing 18 grains per ton have been regularly passed through the precipitating-boxes, their gold content being reduced to $1\frac{1}{2}$ grains per ton. In round numbers we may say that 1 gram of gold is recovered from 1 cubic metre of solution, while 0·1 gram is left in the solution. Even from the point of view of the physical chemist we are here in presence of solutions of a very remarkable order of dilution. A solution containing 1 gram per cubic metre is in round numbers N/200,000, and the weaker solution containing 0·1 gram is N/2,000,000. It is convenient to remember that the latter contains a little more than $1\frac{1}{2}$ grains per ton. In experiments on the properties of dilute solutions the extreme point of dilution was reached by Kohlrausch, who employed solutions containing 1/100,000 of a gram-molecule of solute per litre for his conductivity experiments. These solutions were therefore twice as strong as the gold solution with 1 gram per cubic metre, and twenty times as strong as the

[1] Since the above was written a series of observations has been made on the influence of low temperature on the tenacity of pure metals in the amorphous condition. These observations will form the subject of a separate communication to the Section.

more dilute solution. This fact must be my excuse for placing before you the results of a few simple calculations as to the molecular distribution in these solutions, which have certainly given me an entirely new view of what constitutes a really dilute solution from the molecular point of view.

In estimating the number of molecules in a given volume of solution the method adopted is to divide the space into minute cubical cells, each of which can exactly contain a sphere of the diameter of the molecule. In this way a form of piling for the molecules is assumed which, though not the closest possible, may quite probably represent the piling of water molecules. Taking the molecular diameter as $0{\cdot}2\times10^{-6}$ millimetres—a figure which is possibly too small for the water molecules and too large for the gold —it is found that a cubic millimetre of solution contains 125×10^{15} molecules, or 125 quadrillions. The head of an ordinary pin, if it were spherical, would have a volume of about 1 cubic millimetre.

If these water molecules could be arranged in a single row, each molecule just touching its two nearest neighbours, the length of the row would be 25,000,000 kilometres. A thread of these fairy beads, which contained the molecules of one very small drop of a volume of 6 cubic millimetres, would reach from the earth to the sun, a distance of about 150,000,000 kilometres.

In a solution containing $1\frac{1}{2}$ grains of gold per ton, or 1 decigram per cubic metre, the ratio of gold molecules to water molecules is as 1 : 193,000,000. Each cubic millimetre of the solution, therefore, contains 6,500,000,000 gold molecules. If these are uniformly distributed throughout the solution each will be about 400 micro-millimetres, or 1/60,000 of an inch, from its nearest neighbours. This is not really very wide spacing, for the point of the finest sewing-needle would cover about 1,500 gold molecules.

If a cubic metre of solution could be spread out in a sheet one molecule in thickness it would cover an area of 1,680 square miles, and nowhere in this area would it be possible to put down the point of the needle without touching some hundreds of gold molecules simultaneously.

According to Prof. Liversidge, sea-water contains on the average about 1 grain of gold per ton. If this is the case, then the above figures for the dilute cyanide solution apply with only a slight modification to sea-water. No drop, however small it may be, can be removed from the ocean which will not contain many millions of gold molecules, and no point of its surface can be touched which is not thickly strewn with these. From this molecular point of view we must realise that our ships literally float on a gilded ocean!

From time to time adventurers arise who attempt to launch upon this gilded ocean unseaworthy ships freighted with the savings of the trusting investor. In order that nothing which has been said here may tempt anyone to contribute to the freighting of these ships, let me hasten to point out that the weakest of the cyanide solutions here referred to is richer in gold than sea-water is reported to be. The practical conclusion from this comparison is sufficiently obvious. If the cyaniding expert, whose business it is to extract gold from dilute solutions, finds that it does not pay to carry this extraction beyond a concentration of 2 or 3 grains per ton, even when the solution is already in his hand, and when, therefore, the costs of treatment are at their minimum, how can it possibly pay to begin the work of extraction on sea-water, a solution of one-half the richness, which would have to be impounded and treated by methods which could not fail to be more costly in labour and materials than the simple process of zinc-box precipitation? It is generally unsafe to prophesy, but in this case I am rash enough to risk the prediction that if ever the gold mines of the Transvaal are shut up it will *not* be owing to the competition of the gold resources of the ocean.

In these calculations with reference to the dilute cyanide solutions it is assumed that the gold molecules are uniformly distributed, that they are practically equidistant from each other. There appears to me to be considerable doubt whether we have any right to make this assumption. Leaving out of account for the moment the action of the water molecules, it would appear that as long as the gold molecules are so numerous that a uniform distribution would bring them within the range of each other's attraction, we can imagine that all submerged molecules would be in equilibrium so far as the attractions of their own kind are concerned, being subjected to a uniform pull in all directions. This condition would certainly make for uniform distribution. But when the distance between them exceeds the range of the molecular forces, it is evident that an entirely new condition is introduced, and it seems not improbable that the widely distributed molecules would tend to drift into clouds in which they are brought back within the range of these forces. The range of the cohesive forces in water and aqueous liquids is usually taken from 50 to 100 micro-millimetres, and I am disposed to think that ten times this amount would not be an excessive estimate of the range in the case of gold. If the range for gold be taken as 500 micro-millimetres, then the gold molecules of the dilute gold solution, which are spaced at 400 micro-millimetres apart, are just within the range of each other's attraction, and their distribution is, therefore, likely to be uniform. But by a further dilution to half concentration, the equilibrium would be liable to be disturbed, and denser clouds of gold molecules would be formed, with less dense intervals between them.

In preparing the zinc boxes through which the gold solution is passed, very great care has to be exercised to ensure that the contact surface of the zinc is used to the best advantage. With this object the packing of the zinc shavings is so managed that the solution is spread over the zinc surface in as thin sheets as possible. The object, of course, is to bring as many of the gold molecules as possible into actual contact with the zinc. The gold molecules found in the solution leaving the boxes are those which have not been in contact with the zinc. Yet we have seen that these molecules are still so numerous that they are within 1/60,000 of an inch of each other. If these molecules are in a state analogous to the gaseous state, with diffusive energy of the same order as that of the gas molecule, it is difficult to imagine how they can escape without coming in contact with the zinc surface during their tortuous passage through the boxes and being deposited there. Yet they do escape, even when the velocity of the solution in passing over the zinc surfaces is so slow as 10 cm. per minute or 1·6 mm. per second.

We may regard the condition of these isolated gold molecules, or the more complex auricyanide of potassium molecules, as typical of that of the solute molecules in a dilute solution of any non-volatile solid. They are *solid* molecules sparsely distributed among a multitude of intensely active solvent molecules, the temperature of the solution being many hundred degrees below that at which they could of themselves assume the greater freedom of the liquid or gaseous state. These solute molecules have to a great extent been set free from the constraining effect of their cohesive forces, *but it is important to remember that this freedom has not been attained by the increase of their own kinetic energy as in liquefaction by heat.* Their freedom and the extra kinetic energy they have acquired have in some way been imparted to them by the more active solvent molecules; for, if the solvent could be suddenly removed, leaving the solute molecules still similarly distributed in a vacuous space, they would eventually condense into a solid aggregate. This must be the case, for the non-volatile solute has no measurable vapour pressure at the temperature of the solution. The kinetic energy of the solute molecules is of itself quite insufficient to endow them with the properties of the gaseous or even of the liquid molecule, even when their cohesive forces have been weakened or overcome by separation.

If the energy employed in this separation is not intrinsic to the solute molecule then it must in some way have been imparted by the solvent molecules. It therefore becomes important to compare the energy endowment of one set of molecules with that of the other.

Compared with other solids, ice at its freezing point has very little hardness or tenacity: the cohesion of its molecules has been much relaxed by the great absorption of heat energy between the absolute zero and the freezing point. If an average specific heat of 0·5 over the whole range be assumed, the heat absorption of one gram amounts to 136·5 calories. In the transition to the liquid state at 0° a further absorption of 79 calories takes place, so that

a gram of liquid water at the freezing point contains the heat energy of 215·5 calories. The fact that water has the high vapour pressure of 4·6 mm. of mercury at the freezing point is probably a result of this enormous store of energy. As a liquid, therefore, it is natural to expect that its molecules will exhibit effects proportionate to this great store of energy. This expectation appears to be realised when we consider not only its properties as the universal solvent, but its osmotic and diffusive energy in solutions in which it is the solvent.

To complete the comparison it is only necessary to calculate the heat energy of gold at 0°. Taking its specific heat as 0·032, a gram of gold at 0° contains 8·7 calories. A gram-molecule, therefore, contains in round numbers 1700 calories as compared with 3880 calories in a gram-molecule of water.

Taking into consideration not only this greater store of energy, but also the much smaller cohesive force of water as compared with the majority of solid solutes, there can be no doubt that the active *rôle* in aqueous solutions of this type must be assigned to the solvent, not to the solute molecules.

This leads to the important conclusion that the energy of solution, of diffusion, and of osmosis is due, not to the imaginary gaseous energy of the solute, but to the actual liquid energy of the solvent molecules. When this conclusion is reached a new physical explanation of these phenomena is in our hands, and we are relieved from the strain to the imagination involved in the application of the gas theory to solutions of non-volatile solids.

This transference of the active *rôle* to the solvent molecules does not in any way affect the well-established conclusions based on the laws of thermodynamics as to the energy relations in these phenomena, for it has always been recognised that these conclusions have reference to the average conditions prevailing in large collections of relatively minute units. Wherever the gas analogy has appeared to hold it has not necessarily involved more than this, that the observed effects are in proportion to the number of these minute units in a given volume.

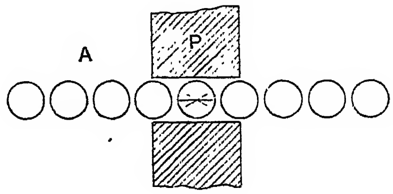
In applying the gas theory to the physical explanation of osmotic pressure it has been the custom to regard this pressure as directly due to the bombardment of the semi-permeable membrance by the solute molecules. But this conception completely ignores the fact that the pressure developed is a hydrostatic, not a gaseous pressure, and that the hydrostatic pressure results directly from *the penetration of the solvent molecules from the other side of the partition.*

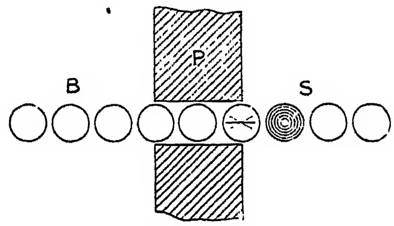
It appears to me more natural to abandon the gas analogy altogether, to regard the molecules as in the solid and liquid condition proper to their temperature, and to apportion to them their respective parts in the active changes according to their obvious endowment of energy.

Applying this view to the case of a solution and a solvent separated by a semi-permeable membrane, it is seen that the pressure rises on the solution side, because the pure solvent molecules on the other side have some advantage for the display of their energy over the similar molecules in the solution. *This effect in its most general form may be attributed to the dilution of the solvent by the solute molecules.* In cases where the osmotic pressure appears to obey Boyle's law the effect is exactly measured by the number of solute molecules per unit volume. But the facts of this position are in no way changed if the effect is taken to be due to the activity of an equal number of solvent molecules, for we then see that each solute molecule by cancelling the activity of one solvent molecule on the solution side permits a solvent molecule from the other side to enter the solution.

What the exact mechanism of this cancellation is there is at present no evidence to show, and the caution originally given by Lord Kelvin with reference to the undue forcing of the gas analogy must also be applied to the suggestion now put forward. But as a means of making the suggestion a little more clear I give here a simple diagram on which A represents a single perforation in a semi-permeable membrane, P, on both sides of which there is only pure solvent. For the sake of clearness the molecules are shown only as a single row. Normally there will be no passage of solvent molecules from side to side, for the average kinetic energy of the molecules on both sides is equal. This state of equilibrium is indicated on the diagram by marking with a cross the molecule which is exactly halfway through the partition.

At B a single solute molecule, S, has been introduced at the right side. If this molecule exactly cancels the energy of one solute molecule at its own end of the row, the equilibrium point will move one molecule to the right, the solvent molecules will move in the same direction, and one of their number will enter on the solution side. So long as the row includes one, and only one, solute molecule, the equilibrium will remain unchanged and no more solute molecules will pass in. If another solute molecule arrives





on the scene, the equilibrium will again be disturbed in the same way as before, and another solvent molecule will pass into the solution.

This mechanism accomplishes to some extent the work of a "Maxwell Demon," in so far at least as it takes advantage of the movement of *individual molecules* to raise one part of a system at a uniform temperature to a higher level of energy.

A Mechanical View of Dissociation in Dilute Solutions.

The view that the phenomena of solution depend on the relative kinetic energy of the solvent and solute molecules appears to apply with special force to the phenomena of dissociation in dilute solutions. Under the gas theory there does not appear to be any reason why the solute molecules should dissociate into their ions. So obvious is this absence of any physical motive that Prof. Armstrong has happily referred to the dissociation as "the suicide of the molecules." Others have proposed to ascribe the phenomenon to what might be called "the fickleness of the ions," thus supposing that the ions have an inherent love of changing partners. These may be picturesque ways of labelling certain views of the situation, but the views themselves do not appear to supply any clue to the physical nature of the phenomena. With the acceptance of the view that the phenomena of solution are largely due to the kinetic energy of the solvent molecules, the phenomena of dissociation also appear to take their place as a natural result of this activity. For consider the situation of an isolated molecule of cyanide of gold and potassium closely surrounded by and at the mercy of some millions of water molecules all in a state of intense activity. The rude mechanical jostling to which the complex molecule is subjected will naturally tend to break it up into simpler portions which are mechanically more stable. The mechanical analogy of a ball mill in which the balls are self-driven at an enormous velocity is probably rather crude, but it may at least help us to picture what, on the view now advanced, must be essentially a mechanical operation.

In importing this mechanical view of the breaking down of complex into simpler molecules we are not without some solid basis of facts to go upon. My own observations have shown that even in the solid state the crystalline molecule can be broken down by purely mechanical means

into the simpler units of the amorphous state; and, further, that the water molecules of a crystal may by the same agency be broken away from their combination with the salt molecules. Since the publication of the earlier of these observations Prof. Spring has shown that the acid sulphates of the alkali metals may be mechanically decomposed into two portions, one of which contains more acid, and the other more base than the original salt. It is important to recognise that in these three apparently short steps the transition has been made from the overcoming of the simple cohesion of similar molecules in contact with each other to the breaking asunder of the chemical union of dissimilar molecules. At each step the solid molecules appear, not as mere ethereal abstractions, but as substantial portions of matter which can be touched and handled mechanically.

The physical properties of a gas are primarily due to its being an assemblage of rapidly moving molecules. These simpler and more general properties can coexist with, and may be modified by, the more complex relations introduced by chemical affinity as it occurs in compound gases and mixtures.

It appears to me quite legitimate similarly to regard the physical properties of a *liquid* as due to its being an assemblage of rapidly moving molecules. The liquid system is highly condensed, and the motions of its molecules are controlled by the cohesive as well as by the repulsive forces. The closer approximation of the molecules may reduce their mean free path to an extremely small amount, or it may even cause their translatory motion to disappear, so that the whole kinetic energy of the liquid molecules may be in the form of rotation or vibration.

As we can imagine a perfect gas, so also may we imagine a perfect liquid, the physical properties of which are as simply related to the laws of dynamics as are those of the gas. But the conditions of the liquid state being also those most favourable to the play of chemical affinity, the internal equilibrium of solutions or of mixed liquids must be a resultant of this affinity together with the primary forces of the ideal liquid state.

An ideally perfect solution—that is, a solution the physical properties of which are determined solely by the number of molecules it contains in a given volume—must consist of a solvent and a solute which have no chemical affinity for each other, so that their molecules will neither associate nor dissociate in solution. Probably only comparatively few solutions will be found which even approximate to this ideal perfection. But it appears to me that the study of the problems of the liquid and the dissolved states may be much simplified by the recognition (1) that the primary physical properties of liquids and solutions are due to the fact that they are assemblages of molecules endowed with the amount and the kind of kinetic energy which is proper to their temperature; and (2) that as these primary physical properties of the liquid and dissolved states may be masked and interfered with by chemical affinity, they should be studied as far as possible in examples where the influence of this force is either absent or at a minimum.

NOTES.

WE regret to learn of the death, at the age of seventy-eight, of Dr. T. R. Thalén, professor of physics at the University of Upsala, and one of the most eminent Swedish men of science. The Rumford medal was awarded to him by the Royal Society for his researches on spectrum analysis, and a gold medal was awarded to him by the Swedish Association of Ironmasters in 1874 for his investigations of magnetic iron ore deposits.

A REUTER telegram from Berlin states that the International Conference for the Investigation of Earthquakes met on Tuesday at the Ministry of the Interior, under the presidency of Privy Councillor Dr. Lewald. All the States which possess organised staffs for the investigation of earthquakes were invited by the German Government to take part in the conference. The conference is expected to last two days.

THE Government Eclipse Expedition in charge of Sir Norman Lockyer, K.C.B., has arrived at Palma, Balearic Islands, where the instruments will be erected for observations of the total solar eclipse on August 30. A Reuter telegram from Madrid reports that the telegraph authorities have decided to frank all telegrams dispatched by members of the various astronomical expeditions regarding observations of the eclipse.

THE London County Council has erected a memorial tablet on No. 14 Hertford Street, Park Lane, where Edward Jenner, the originator of vaccination, resided in 1803; and also on No. 34 Gloucester Square, Hyde Park, where Robert Stephenson, the engineer, resided at one time.

THE death is announced of the Rev. Dr. J. Keith. He was one of the leading educationists of the north of Scotland, and took an active interest in scientific pursuits, especially botany.

THE *Times* correspondent at Wellington, N.Z., states that the Postmaster-General hopes, with the cooperation of Australia, to have wireless telegraphy established across the Tasman Sea within twelve months. The cost will be 28,000*l*.

THE meeting of the tenth International Navigation Congress will be held at Milan from September 24–30. Particulars can be obtained from the secretary, M. Dufourny, 38 Rue de Louvain, Brussels, or from M. Saujast Di Teulada, Villa Real, Milan.

MR. W. E. LANGDON, formerly telegraph superintendent and chief of the electrical department of the Midland Railway, died on Saturday last, August 12. He was for many years a member of the Institution of Electrical Engineers, and was president for the session of 1901–2.

PROFS. RUBERT BOYCE AND RONALD ROSS, of the Liverpool School of Tropical Medicine, left Liverpool on Saturday by the *Campania* for New York. They are proceeding to New Orleans, their services having been offered to the authorities in connection with the outbreak of yellow fever at that port.

A REUTER message from Hong Kong, dated August 12, reports that for nine hours a continuous series of earthquake shocks, two of them prolonged, have been felt at Macao. Slight shocks have been experienced in Hong Kong. An earthquake shock was felt at Chamonix on August 13, at 10.30 a.m. The usual subterranean rumbling noise was heard.

MR. GERALD DUDGEON has been appointed by the Secretary of State for the Colonies to examine and report upon questions relating to the development of the agricultural resources (including cotton) of British West Africa. His title is Superintendent of Agriculture for the British West African Colonies and Protectorates.

THE weather report issued by the Meteorological Office for the week ending August 12 shows that in all the eleven districts into which the British Islands are divided the rainfall since the beginning of the year is below the average, except in the north of Scotland, where the excess is 5·2 inches. The deficiency amounts to 4·6 inches in the north-east of England, and to 3·0 inches in the Midland counties. While at the end of the week in question nearly the whole of England and Ireland were under the influence

of high barometric pressure, an area of low pressure lay over Italy and the Adriatic; these conditions caused an unusually heavy fall of rain over the whole of Switzerland during the night of August 11–12, exceeding 2 inches in amount at several places, with early snowfall at the high-level stations.

IN a recent issue (August 5) the *Academy* directs attention to a curious poetical tribute—composed by a French mathematician—to Archimedes, referring to the evaluation of π, which, set out in thirty places of decimals, is 3·141592653589793238462643383279. It will be observed that each of the thirty-one words in this quatrain contains the number of letters corresponding with the successive numbers in the numerical expression:—

3 1 4 1 5 9 2 6 5 3 5
Que j'aime à faire apprendre un nombre utile aux sages
8 9 7 9
Immortel Archimède, artiste ingénieur!
3 2 3 8 4 6 2 6
Qui de ton jugement peut priser la valeur?
4 3 3 8 3 2 7 9
Pour moi ton problème eut de pareils avantages.

The *Frankfurter Zeitung* reproduces the French verse, and adds a similar effort emanating from a German poet and geometrician:—

3 1 4 1 5 9 2 6 5
Dir, o Held, o alter Philosoph, Du Riesen-Genie!
3 5 8 9 7
Wie viele Tausende bewundern Geister,
9 3 2 3 8
himmlisch wie Du und göttlich!—
4 6 2 6
Noch reiner in Aeonen
4 3 3 8
wird das uns strahlen,
3 2 7 9
wie im lichten Morgenrot!

The *Academy* asks for English parallels to these efforts.

THE fifth instalment of the "Fauna of New England" has just been issued in the seventh volume of *Occasional Papers of the Boston (U.S.A.) Society of Natural History*, and comprises a list of the crustacea, by Miss M. J. Rathbun. The number of species recorded is 390.

WE have received a copy of the sixth annual report of the Plymouth Municipal Museum and Art Gallery, in which are recorded the additions made to the collections during the past year, which are numerous. As regards the biological and geological sections, the committee is apparently of opinion that a miscellaneous *omnium gatherum* is preferable to a representative local collection—an opinion not shared by ourselves. In looking over the list of additions to the geological series, we were somewhat surprised to find the entry of a cast as *Archaeopteryx sinensis*, which is, however, evidently a misprint for *A. siemensi*. We also notice molybdinite in place of molybdenite.

THE latest issue (vol. xv., part ii.) of the *Proceedings of the Cotteswold Naturalists' Field Club* contains two papers dealing with local subjects, namely, one by Mr. L. Richardson on the effects of earth-pressure on the Keuper rocks in the neighbourhood of Eldersfield, and a second, by Mr. C. Upton, on some Cotteswold Oolitic brachiopods. In the latter communication the author, after alluding to the extreme difficulty of determining the various forms of Rhynchonella, feels himself justified in describing two species of that genus as new, and likewise two new terebratulas. Other papers deal with rock specimens from Cyprus, experiences in Korea, and certain early Indian stone monuments.

THE third part of vol. xxv. of *Notes from the Leyden Museum*, issued on April 15, comprises eleven short articles dealing with various invertebrate groups, among which one on Trochidæ by Mr. M. M. Schepman, and a second on the collection of chitons in the Leyden Museum by Dr. H. F. Nierstrasz, are illustrated. Among the other contents reference may be made to five by Mr. C. Ritsema on various groups of beetles, and a sixth by Mr. E. Jacobson (communicated by the Rev. E. Wasmann) on the Javan ant *Polyrhachis dives*. It is well known that the oriental ant *Œcophylla smaragdina* has the remarkable habit of employing its larvæ (which have special silk-glands for making their own cocoons) to glue together the edges of leaves for the benefit of the ants themselves, and the Javan species uses its larvæ in the same manner to spin nests.

IN the *Records of the Australian Museum* (vol. vi., part i.) Mr. R. Etheridge describes the fore-part of a huge fish from the Lower Cretaceous of Queensland allied to the well known Portheus and Ichthyodectes of the same epoch. The specimen is provisionally assigned to the former genus, with the designation *I. marathonensis*, in reference to Marathon, its place of origin on the Flinders River. Later on in the same journal Mr. W. J. Rainbow makes an interesting addition to the subject of social spiders. It appears that some time ago the museum received two huge shawl-like webs taken from the Jenolan Caves, the larger of which measures 12 feet in length and about 4 feet in maximum width. Both webs are closely wrought, and are evidently the work of a large community of a spider referred to new species under the name of *Amaurobius socialis*.

To the May issue of the *Proceedings of the Philadelphia Academy* Mr. B. Smith contributes a suggestive paper on senility in gastropods, mainly based on the study of the Tertiary genus Volutilithes. In most extinct gastropods changes of ornamentation may be observed as the earlier are compared to the later whorls; a normal succession of such changes being noticeable, which varies but little in widely sundered groups, although most families display certain distinctive features in this respect. Infancy, youth, and maturity are represented by distinctive styles in the ontogeny of a species, but these stages cannot always, perhaps from the imperfection of the geological record, be correlated with ancestral types. Senile features, of which several usually occur together in the last whorl, do not all necessarily appear at exactly the same time in the ontogeny. Senile species or genera never transmit descendants, being the terminal members of short branches. Evolution among gastropods seems, indeed, to work sometimes rapidly and sometimes slowly, those forms in which it is rapid and bizarre constituting the aforesaid senile offshoots.

REJUVENATION (Verjungung) forms the subject of an interesting communication by Mr. E. Schultz, of St. Petersburg, to *Biologisches Centralblatt* of July 15. Starting with the fact that in the genital chamber of fasting planarians not only may the whole organ be seen to undergo a retrograde development to its original embryological condition, but the differentiated epithelial cells of this organ may be observed to lose their mutual connection, to become rounded, and to resume their embryological state; the author proceeds to argue that periods

of fasting and torpor, together with the phenomenon of encysting, are of great importance in regard to the rejuvenation of tissue, and consequently to the duration of life of the animal. *Primâ facie,* such periods of rest and rejuvenation would seem to imply longevity in the species in which they occur, and it is therefore suggested that such animals as dormice, badgers, bats, moles, bears, hamsters, and tortoises and many other reptiles are in all probability long-lived. Except in the case of tortoises, our information on this point is, however, very defective. On the other hand, some other explanation must be sought for the longevity which is known to occur in many kinds of birds. The paper concludes with speculations and theories connected with the subject.

IN the July number of the *Psychological Bulletin* (ii., No. 7) Mr. Shepherd Franz describes anomalous time reactions in a case of manic-depressive depression.

THE Bulletin of the Johns Hopkins Hospital for July (xvi., No. 172) contains an interesting contribution to the history of medicine in Maryland during the revolution (1775–1779) by Dr. Walter Steiner, various medical articles, proceedings of societies, &c.

THE *Journal of Anatomy and Physiology* for July (xix., part iv.) contains papers by Dr. Gaskell, F.R.S., on the origin of the vertebrates deduced from the study of the ammocœtes, by Dr. Wright on skulls from the round barrows of east Yorkshire, by Dr. Cameron on the development of the retina in Amphibia, and a report by Dr. Bertram Windle on recent teratological literature, together with several articles of anatomical interest.

THE *Journal of Hygiene* for July (v., No. 3) contains papers on canine piroplasmosis by Drs. Nuttall, Graham Smith, and Wright, and one on bovine piroplasmosis by Mr. Mettam. Dr. Boycott details an experimental case of skin infection with ankylostoma, and Mr. MacConkey contributes an important paper on lactose-fermenting bacteria in fæces. Colonel Leishman, Captain Harrison, and Lieuts. Smallman and Tulloch describe very fully an investigation upon the blood changes following anti-typhoid inoculation; this and several other interesting papers complete the contents of an excellent number.

IN a report on the metropolitan water supply, Dr. Scott Tebb, the public analyst for Southwark, points out that five out of the seven committees of inquiry which have investigated the quality of the Thames water have condemned the river as a source of domestic supply to the metropolis, that the quality of the water as indicated by analysis has shown no substantial improvement during the last thirty years, that the river is extensively polluted, and that it is doubtful if this can ever be prevented. He therefore recommends that London should as soon as possible abandon the Thames as a source of domestic supply, a conclusion neither new nor novel. But when in the body of the report it is stated that "we know nothing of the essential cause of either typhoid fever or cholera, and the medical profession is as much in the dark now as it was 40 years ago" (respecting these diseases), it becomes doubtful how much weight should be attached to Dr. Tebb's conclusions. A large portion of the report is filled with abstracts from papers and books, mostly old, attempting to show that the cholera vibrio and typhoid bacillus have nothing to do with the respective diseases, the overwhelming evidence on the other side being completely suppressed.

A NUMBER of new plants or new localities for previously recorded Indian plants are given in Nos. 4 and 5 of vol. lxxiii., part ii., of the *Journal of the Society of Bengal*. Dr. Prain records several new species from Sikkim, including a Geum and a Potentilla, which are figured, five new species from Burma, and two new orchids from Chota Nagpur. Also Dr. Prain and Mr. Burkill have a note on a new yam, not, however, fit for food, which was collected abundantly in Burma. In another note Mr. J. R. Drummond describes a new Scirpus from Baluchistan, with some allied species.

IT is characteristic of the Americans that when they took over the Philippines they accepted also the responsibilities thereby entailed. In 1837 Father Blanco published a "Flora de Filipinas," enumerating more than a thousand species and varieties; the descriptions were in many cases imperfect, Blanco's knowledge of the plants of neighbouring countries was slight, and unfortunately his herbarium has been lost, so that except where types have been preserved in European herbaria, identification has been most difficult. Mr. E. D. Merrill has prepared a review of the three editions and appendix, of the flora to summarise present knowledge and to provide a basis for further identification by collectors; the volume forms No. 27 of the Publications of the Bureau of Government Laboratories, Manila.

IN the Botanic Gardens at Brussels special facilities have been provided for students for many years in the matter of plant collections, notably of economic, also of officinal and poisonous plants. More recently, in 1902, it was decided to lay out four groups of plants which should be geographical, systematic, evolutionary (phylogenique), and physiological (éthologique), in addition to a group of xerophytes. Copies of the pamphlets explaining the arrangements and the nature of the collections, which are supplied to students, have been received. The evolutionary collection is designed to illustrate variability, heredity, and the origin of new varieties and species. The plants that constitute the "collection éthologique" have been selected on account of their showing special developments, whether for nutrition, reproduction, or some other purpose. A house has been devoted to xerophytes ever since Demoulin's collection was presented in 1882; this has been extended, and a novel feature of the present system is the arrangement of a number of species of cactus as a practical exhibition of an evolutionary series.

MONEY-BOXES in the form of mammæ are made in Germany and Italy, and these form the subject of a paper by F. Rosen in *Globus* (lxxxvii. p. 277). In olden times the mamma was the symbol of abundance, blessings and wealth, therefore this form is peculiarly appropriate for money-boxes; but money-boxes are not ancient. In prehistoric times vessels were frequently made in the form of mammæ, and they are still so made by the folk. The author refers to the pomegranate as an ancient symbol of riches and good fortune; one half of it has some resemblance to a mamma, and the numerous seeds it contains suggest fertility. The mamma was certainly a luck-symbol, and Astarte, Aphrodite, and Isis were luck-goddesses. Astarte, Venus, and Isis were protective patronesses of sailors. He refers to the fact that one often finds money-boxes in the form of pigs; the "lucky pig" is an extremely common talisman in Germany. Pregnant sows were offered to Demeter or Ceres because of the great fertility of this animal. Leland ("Etruscan Roman Remains," p. 255) says, "Ceres was pre-eminently a

goddess of fertility, therefore of good luck and all genial influences; hence little gold and silver pigs were offered to her, and also worn by Roman ladies, partly to ensure pregnancy, and partly for luck."

The recent issues of the *Monthly Weather Review* of the U.S. Weather Bureau contain, *inter alia*, some important articles by Prof. Bigelow on the application of mathematics to meteorology, on the diurnal periods in the lower strata of the atmosphere, and on the observations with kites at the Blue Hill Observatory, from 1897–1902. In the first-named paper, the author points out that no branch of modern science has suffered more severely than meteorology by the misapplication of good mathematics to good observational data, and that the results of recent balloon and kite observations show that nearly the entire range of general theory of the circulation of the atmosphere must be pronounced a misfit. We think we are safe in saying that no other meteorological journal can compare with the *Monthly Weather Review* in its endeavour to popularise meteorological science, by the publication of original articles, reprints, and translations from foreign papers. The ordinary meteorological tables are based on data from about 3583 stations, some of which belong to countries outside the United States. Since December, 1904, the Weather Bureau has received a large number of reports giving simultaneous observations over the Atlantic and Pacific Oceans made at Greenwich—noon. These are charted, and, with corresponding land observations, will form the framework for daily weather charts of the globe. As a further instance of disseminating useful information, we may refer to an article on forecasting the weather and storms, by Prof. W. L. Moore, in the *National Geographic Magazine* for June, illustrated by a number of weather charts. The author points out, with justice, that to anyone who will read the text, and carefully follow the charts which illustrate and make it clear, the daily weather chart will be an object of interest as well as of pleasure and profit. Every step taken, from the receipt of the observations to the publication of the weather chart and preparation of forecasts, is explained with clearness and precision.

Several simple forms of instruments affording a rapid and accurate means of determining the paths of refracted and reflected rays through any optical system are described by Mr. J. R. Milne in the *Proceedings of the Royal Society of Edinburgh* (vol. xxv., p. 806):

It is well known that the minimum potential of a point discharge is increased by the discharge, a blunting or powdering of the point occurring. That the blunting is, however, not responsible for the rise in potential appears evident from a series of experiments made by Mr. F. R. Gorton and described in the *Verhandlungen* of the German Physical Society (vol. vii., p. 217), where it is shown that under the influence of either an ultra-violet radiation or the radiation of radium the blunted point recovers its original value for the minimum potential. The blunting of the point is thus a minor factor in the question, and the conditions are investigated in which constant, reproducible values can be obtained so that the subject may be more fully investigated.

In the July number of the *American Journal of Science* Mr. D. Albert Kreider describes a special form of voltameter in which the accuracy and sharpness of the volumetric method of estimating iodine by means of sodium thiosulphate are utilised. A special form of potassium iodide cell is adopted in which iodine is liberated by the action of the current; its amount is then readily ascertained by direct titration. The results obtained agree very closely among themselves if a certain current be not exceeded, the difference then not exceeding 1 part in 10,000; but the results are uniformly higher by 0·06 per cent. to 0·09 per cent. than are shown by a silver voltameter placed in the circuit. The rapidity and simplicity of the method should adapt it for practical application.

Prof. Balbiano, writing in the *Atti dei Lincei*, xiv., 12, gives an account (read June 18) of the work of Prof. Augusto Piccini, whose death occurred on April 16. While Piccini's most important researches were connected with the periodic law of Mendeléeff, attention is directed to a little-known article on oxygenated water written by him two years ago for the "Encyclopædia of Chemistry," in which the theory was advanced that the atoms of oxygen which it contains are in the form of a combination inferior to that of water.

An interesting application of the mathematical theory of elasticity is given by Prof. Vito Volterra in the *Atti dei Lincei*, xiv., 12. The problem is that of an elastic ring or hollow cylinder of rectangular radial section from which a slice is removed and the separated parts joined together, and the two cases are considered where the fissure is radial and where the portion removed is of uniform thickness. From calculation, the author found expressions representing increase of internal length, decrease of external length, and distortion of the lateral surface of the cylinder into a form concave outwards, and experiments conducted with actual cylinders of caoutchouc closely reproduced all the results of calculation.

Dr. Roberto Bonola, of Pavia, discusses in the Lombardy *Rendiconti*, xxxviii., 11, the theorems of Padre Gerolamo Saccheri on the sum of the angles of a triangle, in connection with Dehn's researches, Euclid's axiom of parallels, and the postulate of Archimedes. Saccheri's investigations were published at Milan in 1793 under the title "Euclides ab omni naevo vindicatus," and were based on the consideration of "bi-rectangular isosceles quadrilaterals," this term being used to designate a quadrilateral ABCD having $AB=CD$, and

$$\text{angle } ABC=BCD=90°.$$

In ordinary space such a quadrilateral is a rectangle. Padre Saccheri gives a proof that if one bi-rectangular isosceles triangle has its remaining angles acute, right, or obtuse, the same property will be true of every other such quadrilateral. From this he deduces that if one triangle has the sum of its angles greater to, equal to, or less than two right angles, the same will be true of every other triangle, *i.e.* the property commonly known as Legendre's theorem on the angles of a triangle. Dr. Bonola refers to Dehn's work in proving that Legendre's theorem is independent of the postulate of Archimedes, and he gives corresponding proofs in connection with Saccheri's work.

A sixth edition of Mr. A. B. Lee's "Microtomist's Vade-mecum: a Handbook of the Methods of Microscopic Anatomy," has been published by Messrs. J. and A. Churchill. The first edition of the work appeared in March, 1885, and was reviewed in our issue of June 18 of the same year (vol. xxxii. p. 147). Many of the suggestions made on that occasion have since been adopted. The text of the book has been even more condensed than in the last edition, and this plan has given room for much new matter. The chapter on staining with coal-tar colours

has been removed, this subject being now dealt with in the general chapter on staining, which has been re-written. The chapters on connective tissues, on blood and glands, and on the nervous system have been thoroughly revised and considerably amplified. Explanations relating to the principles of technical processes have been included in general chapters, and do not in this edition occur under the special sections.

OUR ASTRONOMICAL COLUMN.

THE PLANET MARS.—In No. 360 of the *Observatory* Mr. Wesley discusses the photographs of the planet Mars which Mr. Lowell recently published. Mr. Wesley has made a very careful study of the six prints, and has been able to distinguish easily, on one or another of them, the features named by Mr. Lowell. He is not, however, prepared to corroborate the opinion expressed by the latter that the photographs confirm the fact that the so-called "canals" are *continuous lines*, for imperfect definition might render a row of dots as an unbroken line. As the Lowell photographs are too small to reproduce satisfactorily, Mr. Wesley has made a composite drawing showing all the features seen on any of the prints, and this is given as a frontispiece.

In the same journal Mr. Denning gives, among other planetary observations, an account of his recent areographical researches with a 12½-inch Calver reflector, using a power of 300. He is very certain of the actual existence of the features termed "canals," many of which he was able to identify quite easily. He regards "canals," however, as an unfortunate designation for the irregular, frequently knotted streams of shading, which are by no means straight or narrow, but have a perfectly natural appearance, and says:—"The idea that they are clearly cut lines, suggestive of artificial origin, may be dismissed as a mere conjecture unsupported by reliable evidence."

Major Molesworth, of Trincomalee, Ceylon, has recently communicated to the Royal Astronomical Society a record of his observations of Mars during the opposition of 1903. These observations were made, under excellent conditions, with a 12¾-inch Calver reflector, generally employing a power of about 450. An abstract of this paper, giving the principal tables and conclusions, appears in No. 8, vol. lxv., of the *Monthly Notices*, accompanied by six beautiful drawings showing the chief characteristic features of the Martian surface during the opposition. As his results testify, Major Molesworth has made a long and laborious study of this planet with great zeal, and he has not the slightest doubt as to the reality of the "so-called canals." These markings do not, however, appear to him as continuous definite lines, but rather like "streaky" lines such as would be drawn on very rough paper with a rounded crayon or stump. He records several instances of gemination, and offers a natural explanation of the phenomenon. On six occasions he observed projections either on the limb or the terminator. In conclusion, he proposes a new classification of Martian features, and discusses the several "contrast" and "illusion" theories which have been opposed to the reality of the "canals." Likening these peculiar markings to those seen on Jupiter, he concludes that if the latter be accepted as real—as they undoubtedly are—then the similar ones on Mars cannot, on any logical basis, be ascribed to illusion.

THE RINGS OF SATURN.—Observing at Aosta (Italy) during the later months of 1904, MM. Amann and Rozet noted a novel feature on Saturn's rings. On October 20 M. Amann saw a sharp, accentuated marking, or shadow, on the rings some distance from the outer edge of the shadow cast by the planet itself, and having a curved form concave towards the planet. Between October 20 and November 15 this new feature was not seen, although numerous observations were made under favourable conditions. After November 15 the shadow was seen repeatedly, and it was then noticed that that part of it which was projected on the inner ring was always broader and more accentuated than the other part. Between December 22 and 27 it was seen that this broader portion was bifurcated, so that the whole shadow had the form of a capital Y; that the apparition was a shadow was shown by its fixed position relative to the planet, notwithstanding the rotation of the latter and its rings (*Bulletin de la Société astronomique de France*, August).

DECLINATIONS OF CERTAIN NORTH POLAR STARS.—In No. 3440 of the *Astronomische Nachrichten* Dr. Auwers pointed out that in certain hours of right ascension, north of declination +82°, there were gaps containing no "fundamental" stars, and asked that these gaps might be filled. In answer to this request Miss Harriet Bigelow, of the Smith College Observatory (University of Michigan), has determined the places of twenty-one stars situated between declinations +84° 34′ and +88° 55′, and now publishes them in vol. vii. of the *Proceedings of the Washington Academy of Sciences* (pp. 189–249). The instrument employed was the Walker meridian circle, having a telescope of 6·3 inches aperture and a focal length of 8 feet.

THE MINOR PLANET OCLLO (475).—Another set of positions of the interesting asteroid Ocllo, as determined by Mr. R. H. Frost at Arequipa, are given in Circular No. 103 of the Harvard College Observatory. The object was re-discovered on, and its position determined from, a plate taken on June 6, and was also shown on other plates secured on June 7 and 9. The determined positions show that Ocllo seems to be about 4° from its position as computed from the previously published elements. The data now given, together with the positions published in Circulars Nos. 63 and 101, should enable the elements of Ocllo's peculiar orbit to be determined with great accuracy, and to insure against the future loss of this planet.

THE ROYAL UNIVERSITY OBSERVATORY OF VIENNA.—We have just received vols. xv. and xviii. of the *Annalen der k.k. Universitäts-Sternwarte in Wien*, edited by the director, Prof. E. Weiss. Vol. xv. contains a catalogue of 2417 stars the places of which have been determined by Herr F. Bidschof with the meridian circle, and are given for the mean equinox of 1885·0. The instrumental equipment and the methods employed in the reduction are discussed at length. A series of observations of Jupiter made between February 20 and May 1, 1898, by Herr J. Rheden is also described in this volume, and the description illustrated by fifty coloured drawings of the planet, which are given on the two accompanying plates.

Vol. xviii., in the first part, is devoted to the results obtained from the observations of minor planets and comets, made by Dr. J. Palisa with the Grubb refractor of 67 cm. (about 27 inches) aperture during the years 1899–1901. The observations of seven comets and four nebulæ are included, and the whole of the results are tabulated at the end in a handy form for reference. This volume is completed by the meteorological results obtained in 1901, 1902, and 1903, the pressure, temperature, &c., being given for 7 a.m., 2 p.m., and 9 p.m. on each day.

THE STATE AND THE CLAYWORKER.[1]

IT is the purpose of each of these works to supply the members of the clay industry, in the State to which it refers, with an account of the geological relationships, the mode and place of occurrence, and the chemical and physical properties of the raw clays both worked and unworked. The manufacturing processes of various types of ware are also described as they are practised in the State, with numerous details of physical tests that have been applied to them.

The subject has been treated upon very similar lines in both reports; the Iowa volume, however, contains more information upon the practical manufacturing side; it devotes a chapter to the selection and upkeep of power plants, and has a fuller account of different forms of kiln; there is even a section dealing with the composition of the fuels used in burning the clays. But this volume

[1] "Clays and Clay Industries of Iowa." By S. W. Beyer, G. W. Bissell, I. A. Williams, J. B. Weems, and A. Marston. Iowa Geological Survey, vol. xiv. Pp. xi+664. (Des Moines: Iowa Geol. Survey, 1904.)

"The Clays and Clay Industry of New Jersey." By H. Ries and H. B. Kümmel, assisted by G. N. Knapp. Geological Survey of New Jersey, vol. vi. Final Report. (Trenton, N.J.: Geological Survey of New Jersey, 1904.)

suffers somewhat in comparison with the New Jersey one through faulty editing; there are many more diagrams in the former than in the latter work, but they are sometimes too small for the matter they contain (p. 572); they are rather untidy in appearance, and are frequently inserted sideways in the text when they should be upright. The chemical portion is unnecessarily duplicated, and the important table of analyses (p. 344) is rendered useless for ready reference by the complete omission of silica.

Both books are provided with maps of the geological distribution of the clays, with abundant photographic illustrations of varying degrees of value, with a directory of the clayworkers in the State, and fairly numerous references to the literature of the subject. In each case the section dealing with pottery is weak.

Prof. Ries still maintains that the most generally useful way of expressing the chemical nature of a clay is through the ultimate analysis, though he admits the value of the so-called "rational" analysis in the case of the higher grade clays; with this view we are entirely in accord. Messrs. Beyer and Williams appear to lean somewhat towards the "rational" analysis, and have given the results in this form along with the ultimate analysis—a useful custom. Their method of dividing the ultimate analysis into "sand and clay," "total fluxes," and "moisture, CO_2 and SO_3," is convenient. The influence of titanium on the fusibility of clay is rightly emphasised by Ries; in this country it has been very generally neglected in analyses.

The physical tests applied to clay products were:—compression tests, transverse tests, absorption tests, and freezing and thawing (Iowa only); of these, the second is held in highest esteem; it is certainly far superior to the crushing test in most cases, but we are among those who do not agree with Prof. Marston that for *paving* brick it can take the place of the "rattler" test; the objections he urges against the latter may be applied with equal force to the former, while he admits that the action of the "rattler" approximates more closely to the kind of wear to which paving bricks are subjected in actual use.

From a multitude of councillors we expect wisdom; it is none the less true that if the councillors will not consult one another we are apt to get only confusion. Everyone who publishes some results of physical tests of clays and clay wares seems to think that these should become recognised standards at once. The two authorities here cited are no exception; each one stoutly believes that its own favoured methods should be adopted for general use. There is here a satisfactory unanimity as to the kind of test required, but when we come to details of application, we find considerable divergence of practice in precisely those points which together go to constitute a standard test.

Thus in obtaining the modulus of rupture in the "transverse" test of bricks, New Jersey employs rounded knife-edge contacts alone, while Iowa interposes steel bearing-plates between the brick and the knife-edges; in the crushing and absorption tests New Jersey uses half a brick, Iowa grinds out from the brick a 2-inch cube; again, the former measures linear shrinkage and calculates the cubic shrinkage, the latter reverses the process, using a Seger volumeter for the purpose. For estimating texture (fineness of grain) Iowa employs a modification of Whitney's method, New Jersey uses a centrifugal apparatus. Further, there is an important difference between the methods of collecting materials; Prof. Marston asks for a fairly large consignment to be sent by the manufacturer, and tests twenty or more bricks in the transverse way; on the other hand, members of the New Jersey Geological Survey staff pick out five to seven representative bricks on the spot, and send them to be similarly tested by Prof. Ries. Useful though these tests may be for local reference, it is evident that a standard series of tests will never be arrived at by such isolated endeavours; indeed, we cannot help feeling that in these and similar publications there is much duplication and waste of energy through the lack of a little coordination.

There will be diversity of opinion as to the expediency of the State taking upon itself the task of publishing tests of manufactured wares; it stands in the same relationship to producers as to consumers, yet, while such publications may be supposed to benefit the latter class uniformly, a considerable injustice might conceivably be done to one of the former the ware of which took a lower place in the scale. This danger is exemplified to some extent in the Iowa report, which mentions the names of firms in conjunction with the results, and the effect is too much like an advertisement. New Jersey adopts the plan of publishing the laboratory number of the test; the manufacturer has the result communicated to him privately. For our part we doubt the wisdom of such publication, except upon lines similar to those on which watches and thermometers are tested in this country.

But good maps of the distribution of the clays, the preparation and collection of comparable data of the physical and chemical properties of the *raw* materials, experiments on the results of blending hitherto unworked clays with one another and with known clays, and the coordination of the information and samples in a manner accessible to all, is the legitimate duty of a State department, and of the utmost value to all sections of the community.

The Geological Surveys of Iowa and New Jersey have performed most of these duties in a manner which cannot fail to be appreciated. When we remember that in addition to this Geological Survey work there is in each State a well equipped ceramic laboratory for testing and for instruction in the manufacture of all grades of wares—the department of ceramics in the State College of New Brunswick has an outfit in the brick-making section capable of turning out 20,000 bricks per day—we are constrained to turn our eyes to our own State, where we see the capital pioneer effort of an individual, George Maw, nearly fifty years ago—and what beside? "Comparisons," as Mrs. Malaprop says, are "obvious."

THE CEREBELLUM: ITS RELATION TO SPATIAL ORIENTATION AND LOCOMOTION.[1]

As the cerebellum is well represented in the lowest vertebrates and undergoes relatively little change in form with the higher development of the rest of the brain, it must be regarded as a fundamental structure of the vertebrate nervous system. This may be one of the reasons that much interest has centred in its study and in the attempt to define its functions in exact physiological terms. Though Willis (Oxford, 1660) noted the intimate connection between the cerebellum and pons Varolii, and recognised that the trapezial fibres of the latter are a cerebellar and not a cerebral system, and though Majendie laid the first foundations of our knowledge of its functions, it has only been of recent years that we have gained, chiefly from the work of Luciani and the workers who followed him, satisfactory insight into its anatomy and physiology.

In the lecture, Sir Victor Horsley analysed the conclusions on its functions which have been obtained by the destruction and stimulation methods of study, and in addition contributed from his clinical and laboratory experience some facts which help to elucidate the *rôle* it plays in our nervous economy.

In the first place all recent work confirms the conclusion formulated years ago by Edinger, that the cerebellum is essentially an organ for the reception of certain sensory impulses. Systems of fibres ascending from the spinal cord convey to it part of the sensory impulses which enter through the dorsal roots from the cutaneous and more deeply placed peripheral nerves. These tracts of fibres end in the cerebellum exclusively in its vermis or middle lobe. To the vermis also come direct root fibres of the vestibular nerves which collect from the semi-circular canals, the organs of the special sense of orientation in space, the sensations of change of position and of the position of the head in space. The lateral lobes of the cerebellum, on the other hand, are in connection through the pontine grey matter with the temporal lobes and with the kinæsthetic cortex of the forebrain. All these systems which conduct to the cerebellum end in its cortex, and

[1] Abstract of Boyle Lecture delivered by Sir Victor Horsley, F.R.S., before the Junior Scientific Club of the University of Oxford, June 5.

from the latter—and this is a new fact of great significance—no true efferent fibres arise. The efferent or motor mechanism of the cerebellum is contained in its nuclei, the system of roof nuclei being in connection with the cortex of the vermis, the nucleus dentatus with that of the lateral lobe. The cortex of the cerebellum is thus the special organ for the reception of sensory impressions, while its nuclear system may be regarded as its motor or efferent mechanism.

The functions of the cerebellum must be studied in relation to the sensory impressions it receives and to the activity of other centres. While it is the cortex of the forebrain which consciously appreciates and records our sensory impressions and initiates purposeful actions, it is the cerebellum which automatically preserves our equilibrium, guides our locomotion, and assists to regulate our finer movements. Thus its functions are in part reflex or involuntary, dependent on the sensory impulses which reach it directly or through the forebrain, and in part to coordinate and regulate the muscular contractions generated in the kinæsthetic cortex, especially those which result in movement in space and those on which the maintenance of equilibrium depends. The accuracy of equilibration is necessarily dependent on our knowledge of our position in space. This is obtained chiefly by vision, but as our visual fields are small in relation to the space in which we exist, sight must be supplemented by the power to turn the head and eyes in the three planes of space. There is conclusive clinical and experimental evidence that the coordinated execution of these movements is largely represented in the ponto-cerebellar centres. The sense of touch is also a valuable aid in spatial orientation, for though by touch the body can be aware only of the surface with which it is actually in contact, we can explore, as blind men do, our neighbourhood by the movements of our limbs. The memory of space so obtained is stored up in the kinæsthetic cortex, and disease of this region diminishes or destroys our knowledge of points on the surface of our body so far as their precise position in space is concerned, and consequently the effective movement of the limb. It has been long recognised that one of the most prominent signs of destructive lesions of the cerebellum is the inability to move a limb in a coordinate manner towards any point, but it appears probable from some not yet concluded observations of the lecturer that the faculty of localisation of points of the body in space is also defective with disease of the cerebellum. The touch sensations from the portions of our body resting on our base, the pressure sensations in our joints, and the sensations of tension in our muscles are also requisite for the automatic maintenance of equilibrium. These are some of the sense impressions which pass to the cortex of the vermis by the anatomical tracts referred to.

It would appear that the cortex of the vermis receives the sensory impressions necessary for movement in the anterolateral plane and for bending backwards and forwards; with lesions of this part there is a tendency to fall forwards or backwards. The lateral lobes, on the other hand, receive through the middle peduncles, as Majendie demonstrated, the stimuli necessary for rotation on the longitudinal axis.

From the cortex of the cerebellum, which is constantly receiving these waves of sensory impressions, the cerebellar nuclei collect the properly associated impulses which regulate and reinforce the purposeful movements and the automatic actions of the individual.

This latter position has been established by the researches of Dr. Clarke and the lecturer during the past three years.

Luciani's discovery that the cerebellum is also a source of energy to the muscles, which become asthenic and hypotonic on its destruction, is also fully confirmed by the lecturer's own work.

In conclusion, this sketch of the cooperation of the cerebellum and cerebrum was illustrated by a quotation from Boyle, who said:—"I consider the body of a living man not as a rude heap of limbs and liquors but as an engine consisting of several parts so set together that there is a strange and conspiring communication between them."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE University of Melbourne has received a largely increased endowment from the Government of Victoria on condition of instituting a course for a degree in agriculture. The necessary arrangements for such a course have now been made, and the university is inviting applications in England and America for a professorship of botany and a lectureship in biochemistry in connection with the school of Agriculture. A new professor of anatomy is also to be appointed for the rapidly growing medical school.

THE Drapers' Company has made a further grant of 5000*l*. for an extension of the premises of the East London Technical College. In addition, the company has largely developed its scholarship scheme. Next year nineteen scholarships will be awarded of the value of 40*l*. per annum, tenable at the college for three years. Certain of these scholarships are reserved for women, while others will be awarded in the subjects of the London arts degree. The governors of the college have extended the work by introducing a course in languages and literary subjects. Students taking this course will study under recognised teachers, and be internal students of the University of London. As a consequence of this development, the governors have decided that the college shall, in future, be known as the East London College.

PROBATE has been granted of the will of Mr. John Innes, of Merton, Surrey, who died on August 8, 1904, leaving the sum of about 200,000*l*. for public and charitable purposes. Among other bequests he left his house, the Manor Farm, Merton, and two acres of ground, "to establish thereon a school of horticulture or such other technical or industrial institution as the law will allow, to give technical instruction in the principles of the science and art of horticulture and the necessary physical and mental training incidental thereto; to erect suitable buildings and furnish them, and to provide workshops, tools, plant, scientific apparatus, libraries, reading-rooms, lecture and drill halls, a swimming bath, and gymnasium. If this may not be legally carried out, then to establish in these buildings a public museum for the exhibition of collections of paintings and similar works of art, objects of natural history, or of mechanical or philosophic inventions, and to lay out land for a park."

MR. S. HERBERT COX has been appointed to the professorship of mining at the Royal School of Mines, South Kensington, vacant by the death of Sir Clement Le Neve Foster. In view of the changes in organisation that may be found desirable in the Royal College of Science and the Royal School of Mines after the completion of the investigations now in progress by the departmental committee, the appointment has been made a temporary one. Mr. Cox is an Associate of the Royal School of Mines. After experience as assistant geologist and inspector of mines in New Zealand, he was appointed instructor in geology, mineralogy, and mines in Sydney Technical College; concurrently with his tenure of this office he was employed to give technical lectures at various mining camps in New South Wales, and practised as a mining engineer. Since 1900 he has been entirely engaged in private practice, and has had experience of mining in England, France, Spain, Egypt, the United States, and Canada. Mr. Cox was president of the Institution of Mining and Metallurgy in 1899–1900.

THE *London University Gazette* (August 9) publishes the following announcement referring to the endowment of a chair of protozoology:—"The senate had before them a communication from the Secretary of State for the Colonies, offering the university the sum of 700*l*. a year for five years for the purpose of instituting a chair of protozoology. Of this sum, 200*l*. a year was stated to be a contribution from the Rhodes trustees, and 500*l*. a year to represent a moiety of a grant originally made from the tropical diseases research fund (established under the auspices of the Colonial Office) to the Royal Society for the promotion of research work, and by the Royal Society surrendered for the purpose of endowing the chair. Having considered reports upon this offer from the academic council, and from the board of advanced medical studies and the boards of studies in botany and zoology, the

senate decided to accept the offer, to devote the whole of the 700*l.* a year as salary to the professor, and to set aside a further sum of 200*l.* a year to defray the cost of assistants and laboratory expenses in connection with the chair."

A day higher commercial department is to be opened at the end of September next in connection with the City of London College. The object of this department is to provide a higher education for those who have already had an ordinary secondary education. Hitherto there has been some basis for the charge that higher education has not generally induced students to regard business sympathetically, nor has it exhibited a commercial career attractively. Those engaged in higher education have seldom attempted to show that the study of science, language, and of other subjects is, or can be, related to the conduct of commerce, and that a commercial man will understand his business better if he starts with a groundwork of knowledge which has been deliberately exhibited to him in its relation to the conduct of ordinary business. Those responsible for the new scheme at the City of London College believe that, other things being equal, a youth who has been trained to see the principles which lie behind the facts of commerce, to know how far nature has been controlled by commerce, and commerce by nature; to know the commercial methods of his own and other nations and the reasons for their existence, will make a better business man than one who has had no such training. They believe that there is a mass of experience a judicious selection from which, if assimilated, will save an English youth on his actual entry to commercial life from errors and waste of time. The experiment will be watched with great interest by all who are interested in the various sides of higher education.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 8.—"The Morphology of the Ungulate Placenta, particularly the Development of that Organ in the Sheep, and Notes upon the Placenta of the Elephant and Hyrax." By R. **Assheton.** Communicated by A. Sedgwick, F.R.S.

The formation of the placenta of the Ungulata vera is founded on a system of foldings of the subzonal membrane (or of the trophoblast only), which fit into corresponding grooves in the walls of the uterus, without thickening of the trophoblast layer of the blastocyst, and without destruction of maternal epithelium or other tissue (Sus). Certain parts of the crests of the ridges are produced by local amplification into true villi, into which the splanchnopleure of the allantois subsequently extends (Equus, Bos, &c.).

For this type of placentation, which is caused fundamentally by the folding of the trophoblast, the term plicate is used (placenta plicata), and to this type of placentation it is suggested that the Cetacea, Sirenia, and Proboscidea conform, as well as the Ungulata vera, and possibly the Edentata and Prosimia.

The term placenta cumulata is used for the type of placentation in which the placenta is formed by the heaping up or thickening of the trophoblast layer, among the cells of which accumulation extravasated maternal blood circulates. Destruction of the maternal epithelium probably always occurs. To this type belong the Rodentia, Insectivora, the Hyracoidea, Primates, and Chiroptera. The Carnivora are perhaps intermediate, but, according to Strahl's account, they would be distinctly plicate, while, according to the account of other authors, they are slightly cumulate.

The morphological position of the sheep's placenta, a full account of the development of which is given in the paper, is at that end of the series of plicate forms which closely approximates to the cumulate type.

The placentation of the Ungulata shows that that order is more closely connected with the Proboscidea, and the Sirenia and Carnivora, than with other groups of mammals, whilst the placentation of the Hyracoidea suggests no connection at all with those groups, but is of the cumulate type, and resembles more closely the form found in certain of the Insectivora.

Edinburgh.

Royal Society, July 10.—Dr. R. H. Traquair in the chair.—On the bathymetry, deposits, and temperature of the south-western Pacific: Sir John **Murray,** K.C.B. The region discussed lay to the east and south-east of Australia. Seven of the soundings were in depths exceeding 4000 fathoms and three in depths exceeding 5000 fathoms. Interesting comparisons were made between the bathymetric charts and the temperature charts, and information was also derived from the study of more than 1000 samples of deposits. Globigerina ooze covered about 48 per cent., and red clay about 44 per cent. of the bottom, the remaining 8 per cent. being covered by other deposits. The percentage of carbonate of lime was low in very deep water and in shallow water near islands not bordered by coral reefs. In moderately deep water and in shallow water where the deposit was coral mud, the percentage of carbonate of lime was high. The evidence seemed to point to a continent in the making rather than to a sunken continent.—The varying form of the stomach in man and the anthropoid ape: Prof. D. J. **Cunningham.** The paper was a detailed discussion of the anatomy of the stomach, its changes of form and position at various stages of digestion, the functions of the different parts, and the movements by which digestion was carried out.—The evaporation of musk and other substances: John **Aitken.** The question was as to the nature of the exhalation or emanation which produced the characteristic odour; was it solid or vapour? The test applied was the cloud-producing power in a region saturated with water vapour and suddenly cooled. Experiment showed that when the air was purified of dust particles, but full of musk emanations and water vapour, a sudden cooling produced no cloud. Therefore the emanation must itself be vapour and not solid. The same result was obtained with many other substances, such as spices, chemicals, herbs, and flowers, not one of them giving off solid particles. Evidence was adduced that the dusts of these substances affected the branch of the fifth nerve which serves the nostrils, while the olfactory nerve was sensitive to matter in the gaseous form.

July 17.—Lord McLaren in the chair.—On some points in the geometry of reflecting telescopes with graphical solutions: Dr. James **Hunter.** The real problem in the construction of an efficient reflecting telescope is to find the best size of small mirror and the best position for it, so that the maximum of light and of definition is gained. This the paper discussed in detail, and gave a simple graphical construction by which the required data could be obtained to an approximation sufficient for practical purposes.—Some general principles of absorption spectrophotometry, and a new instrument: James R. **Milne.** The necessary conditions for the photometric comparison of two patches of light, of which one is produced by a ray passing through an absorbing medium, were fulfilled as follows:—(1) By use of a small hole instead of a slit in the collimator a strictly parallel beam of light was secured. (2) By use of a naked flat acetylene flame, the beam was obtained of equal intensity across a normal section, a condition unrealisable by electric arc or lime-light unless heavily screened. (3) By means of a double image prism replacing the ordinary eye-piece of the spectrophotometer telescope it was found possible (*a*) to bring the two patches of light presented to the eye accurately edge to edge, (*b*) to have these patches of some width, namely, that of the telescope objective, (*c*) to secure the coplanarity of the two "faces" of rays which proceed from each point of the edge common to the two patches. The instrument constructed on these lines could also be used as a spectrometer or as a spectropolarimeter for measuring optical rotations.—Note on some generally accepted views regarding vision: Dr. W. **Peddie.** The note referred to some observations on the effect of fatigue in the eye in relation to its power of judging of colour.—On the opacity of aluminium foil to the ions from a flame: George A. **Carse.** The experiments were made in the Cavendish Laboratory, and showed that the aluminium foil was quite opaque to the ions, a result not in agreement with results described by Lebon.—On deep sea-water waves: Lord **Kelvin.** This was a continuation of a paper read last January. By use of Lord Rayleigh's method of

ultimate intersections, a correct diagram was obtained of ship waves in deep and broad water, an approximate representation of which had been given in 1887 (see "Popular Lectures and Addresses," vol. iii.). The numerical calculations and drawings were made by Mr. J. de Graaff Hurster.—On the periods and nodes of Lochs Earn and Trieg: Prof. **Chrystal** and E. Maclagan **Wedderburn.** This was a detailed comparison of the observed periods and nodes with those calculated from the hydrodynamical theory as already given by Prof. Chrystal. The bottom contours were approximated to by piecing together appropriate parabolic functions of the depth; the results of theory and of observation were in good agreement, especially as regards the periods, which are less influenced by local conditions than the node-positions or the amplitudes.—A regular fortnightly exploration of the plankton of the two Icelandic lakes, Thingvallavatn and Myvatn: C. N. **Ostenfeld** and Dr. C. **Wesenberg-Lund.**—Note on the boiling points of solutions: S. N. **Johnson.** It was found that the boiling-point elevation constant C, as calculated from the formula

$$Cw\{1+(n-1)a\}=mWe,$$

where m is the molecular weight of salt used, W the weight of solvent, w the weight of salt added, α the ionisation constant, n the number of free ions, and e the observed elevation of temperature, had widely differing values. The discrepancies clearly arose from the difficulty of getting the boiling point of the solvent. When, however, C was calculated from the formula when for e and w are substituted the increments Δe and Δw, as one passes from solution of lower to solution of higher concentration, satisfactorily concordant results were obtained. The salts studied were the nitrate, chlorate, chloride, and bromide of potassium, and the nitrate and chloride of sodium.—The oxidation of manganese by persulphates: Dr. Hugh **Marshall.**—Influence of cross magnetisation on the relation between resistance and magnetisation in nickel: Dr. C. G. **Knott.** The decrease of resistance of a strip of nickel foil when magnetised transversely to its length was numerically increased when the foil was set in a steady magnetic field magnetising it longitudinally, while the increase of resistance accompanying the application of this longitudinal field was numerically decreased when the foil was set in a steady field magnetising it transversely.

PARIS.

Academy of Sciences, August 7.—M. Bouquet de la Grye in the chair.—Observations of the planet Y.R. (Goertz) made with the large equatorial of the Observatory of Bordeaux: E. **Esclangon.** Observations of this planet were made on July 29 and 30, and the results are given, together with the mean positions of the comparison stars, and the apparent positions of the planet.—On the sidereal day: A. **Pansiot.**—On continued algebraic fractions: M. **Auric.**—On similitude in the motion of fluids: M. **Jouguet.**—On the state of matter in the neighbourhood of the critical point: C. **Raveau.** A criticism on a recent paper on the same subject by MM. G. Bertrand and J. Lecarme. The author contests the views put forward by these authors, and notes that a consequence that they have deduced is a peculiarity of which a complete account is rendered by the ordinary kinetic theory of gases.—On magnetic double refraction. Some new active liquids: A. **Cotton** and H. **Mouton.** A solution of dialysed iron prepared by the method of Bravais undergoes a marked change when heated for some time at 100° C. The double refraction in a magnetic field became greater, four hours' heating making the double refraction forty times its original value; the size of the particles was clearly increased by the heating. Colloidal solutions of iron were also prepared by the method indicated by Bredig for the precious metals. This solution was doubly refracting also, but the variation with the strength of the field followed a different law to the Bravais solution. A solution of iron prepared by the Bredig method in glycerine was also examined. Solutions were also found exhibiting magnetic double refraction which did not contain iron, but minute crystals of calcium carbonate. Reason is shown for supposing that for these effects to be observed the size of the separated particles must lie between certain limits.—On the chloroborates of calcium: L. **Ouvrard.**—Study of the constitution of unsymmetrical dipara-ditolylethane, of the dihydride of 2:7:9:10-tetramethylanthracene and of 2:7-dimethylanthracene: James **Lavaux.**—On the absorption spectrum of manganous salts: P. **Lambert.** The manganese salts used in the research were purified with especial care from iron, since the spectrum of the latter element in the ultra-violet was found to interfere. A diagram is given of the manganese bands for wave-lengths between 557 and 394.—The thermochemistry of the hydrazones: Ph. **Landrieu.** The reaction between some ketones and aldehydes has been determined directly in the calorimeter, and the values thus found compared with those deduced from the heats of combustion determined with the Berthelot bomb. The results of the two methods show a fair agreement.—The mechanical properties of iron in isolated crystals: F. **Osmond** and Ch. **Frémont.** The experiments were made upon crystals of a volume of several cubic centimetres, and included measurements of the extension, compression, hardness, and bending. It was found that the mechanical properties of iron in crystals are a function of the crystallographic orientation. The fragility, very great in the plane of cleavage, is, contrary to the views generally held, associated with great plasticity in the other directions.—The classification and nomenclature of the arable earths according to their mineralogical constitution: H. **Lagatu.**—On the reddening of the vine leaf: L. **Ravaz** and L. **Roos.** A study has been made from the chemical standpoint of the non-parasitic reddening of the leaf of the vine. The results confirm the theories of Bœhm and some other authors on the solution and migration of the carbohydrates in the leaf.—*Sterigmatocystis nigra* and oxalic acid: P. G. **Charpentier.** Oxalic acid is a product of the growth of this mould when cultivated in Raulin's solution, and is still produced when the tartaric acid of this solution is replaced by sulphuric acid. But if the Raulin's solution is deprived of sugar, and the tartaric acid is the only source of carbon, then oxalic acid is not formed.—On the mending of wounds in cartilage both from the experimental and histological points of view: V. **Cornil** and Paul **Coudray.**—On accommodation and convergence in binocular vision: Léon **Pigeon.**—The geological structure of the central Sahara: Émile **Haug.**

Geometrical Conics. By G. W. Caunt, M.A., and C. M. Jessop, M.A. Pp. vi+80. (London: Edward Arnold.) Price 2s. 6d.

THE little book on "Easy Graphs," by Mr. H. S. Hall, is the result of ripe experience, and is intended to lead the beginner by very easy stages and show him all the points that require special attention in squared paper work and the lessons to be learnt therefrom. Great attention is paid to the suitable choice of scales and the proper figuring of the diagrams. Linear graphs with inferences and applications occupy fully half the book, the latter half relating to algebraical equations and graphs of the second degree with one or two cubics. The numerous examples are interesting and suggestive, and all the answers are given at the end. We agree with the author in deprecating the undue employment of graphs, especially as the field in which they may be legitimately used is sufficiently extensive. The book will be deservedly popular.

The "Rudiments of Practical Mathematics," by Messrs. Consterdine and Barnes, is a very excellent treatise, intended more particularly for students above twelve years of age who are preparing for industrial pursuits. The heuristic method is in the main followed, and the material for exercises is largely drawn from the students' own measurements, suitable objects of a simple kind being provided for this purpose, with appliances for measuring lengths, areas, volumes, weights, and times. Thus every rule and process is definitely associated with some direct quantitative application, and the subject assumes a real and living interest and cannot fail to be assimilated. The subject-matter is purposely confined to that which is in daily use in industrial occupations, so that there is time for this to be dealt with in a very thorough manner. In this volume arithmetic, algebra, and geometry are so interwoven that any attempt at separation would appear quite unnatural. Thus when an important principle, say that of proportion, is under review it can be studied and developed with the completeness which its importance demands, arithmetically, algebraically, and geometrically. Students are taught the use of logarithms, and also sufficient trigonometry to enable them to solve right-angled triangles; they use compasses and setsquares, draw simple plans and elevations, and make dimensioned free-hand sketches in pictorial or other projection, and they are introduced to the notion of a vector by means of displacement and velocity diagrams. In some places there may be an insufficient number of examples for the purposes of drill, but altogether the subject is admirably developed and presented; the book is well adapted to its purpose, and its wide adoption would have a very beneficial effect.

The "Elementary Practical Mathematics," by Messrs. Stern and Topham, is a preliminary volume comprising the first nine chapters of a more complete text-book on which the authors are engaged. It relates to physical measurement with exercises based thereon, including the measurements of length, angles, mass, area, volume, specific gravity, with the practical calibration of certain glass vessels. The two first chapters deal with contracted arithmetical processes and squared paper work, but otherwise a knowledge of "theoretical" mathematics is assumed. The work is intended as a first course for the junior forms of schools, and especially for boys preparing for army examinations. The apparatus is fairly comprehensive, and the experiments are well described. The book will be very useful to those arranging a course in an important branch of practical mathematics.

The "First Algebra," by Messrs. Baker and Bourne, is adapted from the first part of the authors' larger work, and, proceeding in the customary order, carries the subject up to quadratic equations and fractional and negative indices. Arithmetical and graphical illustrations are freely introduced, and a special feature of the work is its very easy graduation and the large number of examples, some oral, provided at every stage, so that students using the book properly cannot fail to obtain a full knowledge of the subject. The answers are completely given, and themselves extend to thirty-five pages. The book gives an admirable first course in algebra.

Mr. Shorto's "Algebraical Grounding" is a collection of the definitions, axioms, laws, rules, and proofs belonging to the subject, without examples, and arranged in logical sequence. It is intended as a summary of the oral teaching usually imparted, and could well be used in conjunction with a collection of examples. It includes logarithms, the progressions, and the binomial theorem.

The collection of eight thousand "Examples in Algebra," by Mr. Clay, has been accumulating for the last twenty years, during which time the author has been engaged in teaching the subject in America, and has found that the examples provided in the ordinary text-books are deficient in both quantity and variety, and not regularly graded. The teacher will here find examples in superabundance, increasing in difficulty by almost insensible steps from the simpler

exercises in the use of symbols to the difficult problems in surds, theory of exponents, quadratics, and in arithmetical and geometrical progressions. The work shows no trace of having been influenced by the reform movement going on in this country, but teachers will receive valuable hints and much useful matter by consulting this thorough and extensive compilation.

The "Geometrical Conics" by Messrs. Caunt and Jessop is a preliminary deductive course for students about to enter on a systematic study of analytical geometry. Only the leading properties of conics are dealt with, and these are established when possible from corresponding properties of the circle by the aid of the modern methods of projection. The book is well suited to its purpose.

PANAMA CANAL.

Problems of the Panama Canal. By Brig.-General Henry L. Abbot, U.S. Army. Pp. xi+248. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1905.) Price 6*s.* 6*d.* net.

THE author of this book acquired distinction in hydraulics in early life by the publication, in conjunction with Captain Humphreys, of their well-known "Report on the Physics and Hydraulics of the Mississippi River" in 1861; and, accordingly, this statement of the problems of the Panama Canal, in which hydraulics are so largely involved, by such a high authority, who, as a member of the technical committee of the New Panama Company, devoted seven years to their study, deserves the most careful consideration of the American nation, for whose guidance this volume has been published. It appears at a very opportune time, when the United States Government has undertaken the completion of the works, but has entrusted to a commission of engineers the consideration of the precise designs for the canal.

The chapters on the "New Panama Company," with which the author was connected, "The Rival Routes" of Panama and Nicaragua, the "Physical Conditions of the Isthmus," "The Chagres River," with its torrential floods and difficulty of control, and the "Disposal of Rainfall," all present features of interest, and the last three are essential in a study of the works to be carried out; but undoubtedly the most interesting portion of the book for the British public and engineers generally is contained in the final chapter on "Projects for the Canal." It will be remembered that when M. de Lesseps started the scheme about twenty-five years ago he proposed the construction of a tide-level canal; and the works were commenced on this basis with very inadequate investigations of the nature of the strata to be traversed by the cuttings, especially through the Culebra ridge, and the physical conditions of the locality. When experience had proved the unexpected magnitude of the undertaking, and the unforeseen difficulties to be overcome, the original company, approaching the end of its resources, decided in 1887 to introduce locks, thereby greatly reducing the amount of excavation, and also the time required for the completion of the canal. Eventually, after the failure of the first company, a New Panama Company was formed in 1894 (given by a misprint as 1904 in the introduction); and the works for a canal with locks were slowly proceeded with as funds permitted, until at length, last year, the United States Government purchased the undertaking with the view of carrying it out as a national work. Early this year an engineering committee of the Panama Commission recommended a sea-level canal again, with a bottom-width of 150 feet and a minimum depth of 35 feet, and the necessary duplicate tidal locks near the Panama end, capable of accommodating vessels up to 1000 feet in length and 100 feet in width.

The principal objections to the formation of a canal across the isthmus at sea-level throughout, are the time, difficulties, and cost involved in making a cutting, reaching a depth of 317 feet, in unfavourable strata exposed to tropical rains, and the efficient control of the River Chagres, which crosses the line of the canal on the Atlantic slope in several places, and the floods of which will become a more serious peril to the maintenance of the canal in proportion as the water-level of the canal is lowered. The objection of cost, and, to some extent, that of time, are of considerably less importance in a national than in a private undertaking; but the floods of the Chagres appear liable to prove a standing menace to the safety of a tide-level canal. The Isthmian Canal Commission of 1899–1901 expressed its disapproval of a sea-level project in the following words:—

"The cost of such a canal, including a dam at Alhajuela, and a tide lock at Miraflores near the Pacific end, is estimated at not less than 240,000,000 dollars. Its construction would probably take at least twenty years. This Commission concurs with the various French Commissions which have preceded it, since the failure of the Old Company, in rejecting the sea-level plan. While such a plan would be physically practicable, and might be adopted if no other solution were available, the difficulties of all kinds, and especially those of time and cost, would be so great that a canal with a summit level reached by locks is to be preferred."

The author regards these remaining difficulties as very important; and, after discussing them, and particularly the problems concerning the control of the Chagres, he concludes his book with the following expression of his opinions:—

"It is the unanimous opinion of all the engineers who have had practical experience in canal work, and time to thoroughly study the problem, that no sea-level *projet* without locks, and no sea-level canal, even with a tidal lock, is practicable that would be comparable in ease and safety of transit to one equipped with modern locks, and planned to take advantage of all the desirable elements which the natural conditions offer. Why, then, waste an extra ten or a dozen years, and untold millions of dollars, to execute a scheme which the investigations of thirty-five years have demonstrated to possess only a sentimental merit due to the imagination of M. de Lesseps? Congress and the American people are impatient for the opening of the best possible canal."

OUR BOOK SHELF.

The American Thoroughbred. By C. E. Trevathan. (American Sportsman's Library.) Pp. ix+495; illustrated. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1905.) Price 8*s.* 6*d.* net.

FROM the point of view of the naturalist, the interest of this volume (which is no doubt an admirable guide to everything connected with racing on the other side of the Atlantic) is concentrated on the author's remarks with regard to the origin and development of the American thoroughbred. As a matter of fact, the racehorse in America has been produced mainly from an English ancestry, and is thus essentially of the English type; and the one matter for regret in his treatment of the subject is that the author does not appear to point out any features by which the American breed may be distinguished from its European prototype, as it is difficult to believe that minor differences between the two do not exist. The first thoroughbred imported into America seems to have been Bulle Rock, a horse foaled in England in 1718 and landed in Virginia in 1730. He was a scion of the Darley Arabian, and had also the blood of the Byerly Turk on the maternal side. The product of native-bred mares (that is to say, mainly the descendants of horses imported by the Spanish conquerors, which were themselves largely of Barb blood) by Bulle Rock formed the first foundation of the modern American racing stock. Diomed was another famous English stallion imported into Virginia in the old days; but long after the definite establishment of an American thoroughbred stock, considerable improvement was effected therein by the importation in 1836 of Glencoe, at that time a renowned English horse. Glencoe was by Sultan, and while in England sired Pocahontas, the dam of Stockwell, Rataplan, and King Tom, the three greatest sires the English turf has ever seen, and to one of which almost every living English racehorse can trace descent. With such a sire the future of the American thoroughbred was assured. In conclusion, we may congratulate the author on having added a valuable volume to a valuable library, as well as on having made an important contribution to our knowledge of the ancestry of the American racehorse.

R. L.

The Story of Reptile Life. By W. P. Pycraft. Pp. 212. (London: George Newnes, Ltd., 1905.) Price 1*s.*

THIS is a valuable addition to the "Newnes' Library of Useful Stories." Mr. Pycraft not only writes in a readable and entertaining style, but also has the happy faculty of selecting precisely those facts which enable him to expound general principles. The "Story of Reptile Life" is not an elementary book of natural history in the ordinary sense, but the outline of a really scientific treatise which is not too technical to be understood by a beginner. After some introductory remarks explaining that he has to deal with a race "whose glory has departed," the author proceeds to describe each of the groups of surviving reptiles, with some reference to their immediate ancestors as revealed by fossils. In each chapter he treats first of the most salient points in anatomy, and then proceeds to select a few of the more important living species for detailed notice. The account of the existing reptiles is followed by two chapters on domestic life and reptilian liveries. The book then concludes with chapters on the extinct flying reptiles, land reptiles, and sea reptiles. We have detected no serious errors, though it is difficult to accept all the author's speculations concerning some of the extinct forms, and there are more misprints than ought to be. The book also lacks adequate illustrations. It is, however, a worthy sequel to Mr. Pycraft's earlier "stories" of birds and fishes, and we hope he may soon complete the series by a final volume on the mammals.

Digest of the Evidence given before the Royal Commission on Coal Supplies (1901–1905). Vol. i. Pp. lxiv+474. (London: The *Colliery Guardian* Co., Ltd.) Price 21*s.*

THE *Colliery Guardian* has done useful work in preparing this digest of the evidence given before the Royal Commission on Coal Supplies. The 25,662 questions and answers contained in the official minutes of evidence do not constitute an attractive form of technical literature; but with the matter rearranged and classified under separate heads, and the interrogative converted into the narrative form, it is surprising to find what an enormous amount of valuable information has been got together. With the exception of a brief historical introduction, no comment is made on the evidence, and such additions as the witnesses have found desirable when revising their evidence have been printed as footnotes. The work will be completed in three volumes, the subjects dealt with in the first being the working of thin seams, the limit of depth in mining, waste in working and coal-cutting machinery. There is a good index and a useful bibliography of the subjects discussed. Printed in large type, with the illustrations admirably reproduced, the work forms a valuable companion to the official Blue-books, and, indeed, from the point of view of the mining student, may replace them altogether.

Wasps, Social and Solitary. By George W. Peckham and Elizabeth G. Peckham. With an introduction by John Burroughs. Pp. xv+311; illustrated. (London: Constable and Co., Ltd., 1905.) Price 6*s.* net.

THIS book is founded on a series of papers published some years ago by the Wisconsin Biological Survey under the title of "Instincts and Habits of the Solitary Wasps," with much new matter added. It is a record of very patient field observations on the lines with which Fabre's well-known "Souvenirs Entomologiques" (constantly referred to, and compared by our present authors with their own) have made us familiar.

The wasps discussed are chiefly those which provision their nests with caterpillars and other insects, or with spiders; and the genera noticed are Vespa, Ammophila, Sphex, Rhopalum, Odynerus, Aporus, Crabro, Bembex, Cerceris, Philanthus, Trypoxylon, Pompilus, Tachytes, Chlorion, Pelopœus, Astata, Oxybelus, &c., all of which (Sphex, Bembex, and Chlorion excepted) include British species. Many persons are interested in the habits of insects who have not time or opportunity to observe them for themselves, and to all such we heartily commend this important work on the manners and customs of North American wasps.

W. F. K.

X-Rays: their Employment in Cancer and other Diseases. By Richard J. Cowen. Pp. viii+126. (London: Henry J. Glaisher, 1904.) Price 2*s.* 6*d.* net.

THE author of this work states in his preface that he has made no effort to summarise all the valuable work which has been done in radiotherapy, and he has only tried to select such part as seems to him to be most likely to assist those practitioners in the therapeutic

properties of X-rays, the choice of apparatus, and the technique.

In the first twenty-four pages the apparatus is considered, and the remainder of the work, with the exception of two short chapters, is devoted to brief consideration of a number of skin affections, including malignant disease. The book will certainly be of service to those for whom it is intended, and many practitioners who desire to become acquainted with this new branch of electrotherapeutics will find it a useful introduction. The work is well written and unpretentious, and Dr. Cowen has succeeded in the aim laid down in his preface.

Neue Abhandlungen über den menschlichen Verstand. By G. W. v. Leibniz. Translated, with introduction, by C. Schaarschmidt. Second edition. Pp. lxviii+590. (Leipzig: Dürr'sche Buchhandlung, 1904.) Price 6 marks.

Immanuel Kant's Logik. By G. B. Jäsche. Third edition. New edition by Dr. W. Kinkel. Pp. xxviii+171. (Leipzig: Dürr'sche Buchhandlung, 1904.) Price 2 marks.

Lazarus der Begründer der Völkerpsychologie. By Dr. Alfred Leicht. Pp. 111. (Leipzig: Dürr'sche Buchhandlung, 1904.) Price 1.40 marks.

THE first two of the above-mentioned works appear as parts of the excellent "Philosophische Bibliothek." The translation of the Leibniz into the philosopher's native tongue appears to be all that could be desired, and the introduction gives an analysis of the work. We gather that some 460 explanatory notes are to be found in the succeeding volume of the series. This edition of "Kant's Logik" is intended to supersede the uncritical one of Von Kirchmann, who relied only on the second Hartenstein edition of 1868. The present editor has gone back to the original text of Jäsche, and has also compared the other important editions, the first Hartenstein and the Rosenkranz, both of 1838. The spelling is completely modernised. Prof. Moritz Lazarus was, with Steinthal, the founder of the *Zeitschrift für Völkerpsychologie und Sprachwissenschaft* in 1859, and his works not only contain much sound psychology, but are also permeated by a fine ethical spirit. His long life and labours are here described by a singularly appreciative disciple.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

British Fruit Growing.

THE question of "the diversity of yield from farms in the same neighbourhood" to which you referred in your article on the report of the fruit committee is, as Mr. Alfred Walker remarks, one of very great complexity. No evidence on this subject, however, was offered to the fruit committee by the numerous growers who appeared as witnesses before them, and it would certainly seem to be a subject more suited for investigation at an experimental station than one which could be dealt with by a departmental committee.

Meteorological conditions are, no doubt, primarily responsible for most failures of cropping, and, in a climate such as that of our islands, we can never hope to do more than mitigate the evil effects of inopportune cold. The destruction of the blossoms is generally due—as in 1903—to cooling by radiation, and the best safeguard against this form of cooling is a fairly elevated position, and a lie of the ground favourable to the draining away of the cold air from the plantation. Good air drainage is probably more important in fruit growing than good water drainage. Various means have been investigated for producing radiation by artificial means, but the results have not yet proved themselves to be successful, at any rate from an economic point of view.

The destruction of blossoms, however, is caused sometimes by a low atmospheric temperature produced by means other than surface radiation. This was the case in the present year, when the destructive cooling agent was a cold wind. A warm, low situation, with plenty of shelter, will afford some safeguard against damage from such a source; and these, unfortunately, are just the conditions which will increase the danger from radiation frosts.

There is no doubt, however, that the damage done by a low temperature is not always done in a direct manner. A continued spell of cold weather at the blossoming season is inimical to the activity of the various insects on which pollination mainly depends, and we are not yet in a position to say that a sluggish action of the roots and leaves may not itself be directly detrimental to the process of fertilisation. The number of apples and, still more, of pears which have been imperfectly fertilised, and have, therefore, dropped prematurely, have been very noticeable this year.

What part the nature of the soil plays in modifying the action of cold on the trees is one which is very difficult to foretell or to determine. We can never have two plantations in different soils while being in exactly similar positions; and the question whether a blossom will be reduced to a lower temperature by radiation in the moist air overlying a clay soil than it would be in the dryer air overlying a gravel soil, or whether, if reduced to the same temperature in both cases, it would suffer more in the one than in the other, is a question on which we cannot dogmatise. We must not be misled by the feeling of cold experienced in two such cases by the human subject; indeed, watering the trees and ground is one of the methods suggested for obviating the effects of radiation frosts. Differences of soil, also, will act indirectly in the matter by affecting the root-action and the forwardness of the blossoms.

On one point, however, I think there can be no doubt, namely, that the best safeguard against injury by frost, where frost is inevitable, is a healthy condition of the tree itself. It has been a matter of continued observation that with similarly situated plantations, and with similar trees in the same plantation, those which are most healthy will nearly always suffer least from frost. It is specially noticeable that with trees which are weakly, even when they carry (as will often happen) a great abundance of blossom, injury from frost is very severe, although the abundance of blossom should be favourable to some of these being preserved from destruction.

It is in this direction—the general health of the trees and the raising of healthier and hardier varieties—that success in diminishing loss by frosts will most probably be achieved. It is hardly probable, I think, that much will be effected, at any rate in the case of apples, by raising varieties blossoming late enough to escape frosts. These frosts, as we all know, often occur very late in the year, and though every day by which the blossoming is retarded must, on the average, diminish the risk of its destruction, there would appear to be but little chance of our being able to retard it sufficiently to diminish that risk to any material extent. It must be remembered, also, that though we might raise a late blossoming apple, it is a hundred chances to one that the fruit would be able to compete in the market with known varieties.

The flowers of the large majority of English apples would appear to open within a period of about ten days. Observations made this year on 117 varieties gave a total range of 16 days, but 98 per cent. of these varieties opened within a range of 13 days, and 84 per cent. within a range of 9 days. The extent of the variation, therefore, is not sufficiently large to offer much promise of success in raising a variety which would escape frost by its lateness of flowering. It is noticeable, however, that our English apples appear to be rather earlier in their flowering than varieties belonging to other countries, when all are grown under the same conditions. The results obtained at Woburn this year were as follows, the dates being those of the opening of the first flowers, and the fractions of dates arising, of course, through the taking of the means. The number of varieties under observation are given, and

those termed English include several varieties of foreign origin which are commonly grown in England. In most cases the trees were on the crabstock:—

117 English	May 6·4
36 Scotch	May 8·9
9 Irish	May 9·4
8 French	May 9·0
(1 German	May 4·0)
7 Russian	May 8·6

Another point of some interest in connection with these results may be mentioned, namely, that there is a connection between the earliness of blossoming and the earliness of the ripening of the fruit, though it is so slight that it becomes apparent only when the averages of a considerable number of varieties are taken, and many individual instances may be noticed where the later fruit follows the earlier blossoming:—

37 Early varieties	May 4·7
40 Mid-season varieties	May 6·3
40 Late varieties	May 8·0

This letter, I fear, is already too long, but it leaves unmentioned several points which may be of importance in determining the fruiting of trees.

SPENCER PICKERING.

Artificial Diamonds.

OF the two phases, diamond and graphite, diamond is the denser, and has also the less internal energy. It follows that, if carbon can be crystallised at comparatively low temperatures, the minimum pressure sufficing to determine the diamond form will be lower than that employed in M. Moissan's experiments.

For estimating the transformation temperature corresponding to low pressures, the data available are incomplete; it is here suggested, however, as a tentative result from experiments which are still in a preliminary stage, that the transformation temperature corresponding to atmospheric pressure lies somewhere between 550° C. and 700° C., or not far outside those limits, temperatures having so far been judged only by eye.

A molten alloy of lead with about 1 per cent. calcium appears to be capable of holding in solution some small proportion of carbon, which exists either as free carbon or as calcium carbide; and if the calcium is eliminated from the molten mass, some carbon crystallises out. Steam, for example, converts the calcium into hydrate without attacking the lead. If the reaction has occurred at a full red heat, graphite is found in the crust of lime; if only a very low red heat has been attained, no graphite is found, but a number of very small or microscopic crystals, which have many of the properties of the diamond. The illustration is from a pencil drawing of a very minute crystal, viewed under a magnification of 80 diameters, and drawn on a greatly enlarged scale.

FIG. 1.—Supposed diamond from lead-calcium-carbon solution.

The crystals obtained exhibit mostly faces of the octahedron, modified by the cube and dodecahedron; in no case has any internal flaw or lack of perfect transparency been detected in them. The refractive index is clearly very high, and an attempt to determine it by displacement of focus gave 2·43 (instead of 2·47), any convexity of the refracting surface tending to give too low a value. The crystalline faces are, in fact, generally if not always convex, in many cases strongly so. The crystals adhere tenaciously to clean, dry glass; they are unacted upon by ordinary acids (hot or cold), by cold hydrofluoric acid, and by fused alkali at a red heat. When strongly heated on platinum foil, they burn away, leaving no residue. The quantities at present available are too small for the ready determination of density or hardness.

Negative results were invariably obtained in control experiments on the commercial calcium carbide which was used in preparing the alloys.

Tin may be used in place of lead, but it is freely oxidised by the steam, and the resulting dioxide is troublesome to get rid of. Of other reactions which appear to have yielded minute crystals of diamond, the following may be mentioned:—boiling benzene or toluene in contact with finely powdered potassium dichromate or with concentrated aqueous solution of gold chloride; heating benzene or toluene mixed with carbon tetrachloride or chloroform to 200° C. to 300° C. in a bomb. In the last named reactions, nearly all the carbon separates out in the amorphous form, hydrochloric acid collecting under enormous pressure.

I hope shortly to return to the subject of these experiments, and to make a fitting acknowledgment of my deep indebtedness to Mr. W. J. Hartley, to Messrs. Neville and Heycock, and to other friends.

C. V. BURTON.

4 Chesterton Hall Crescent, Cambridge, August 19.

The Spread of Injurious Insects.

IN 1898 Dr. L. O. Howard forwarded to me a scale insect discovered by Prof. Chaves at Ponta Delgada, Azores, attacking the foliage of the orange tree. The insect proved to be new, and was described as *Lecanium perlatum*. Since that time it has never been reported from any other place; but now I have received some large, flat, dark brown scales on orange leaves from Villa Encarnacion, Paraguay, collected by Mr. Schrottky, and they are this very same *L. perlatum*.[1] This is only one new case to be added to the many already known of scale insects being transported from one side of the world to the other, evidently by human means. It is to be regretted that the British Government, with its numerous tropical colonies and excellent botanical gardens, has not done something to make known the scale insects within its domains. It is true that Mr. E. E. Green, the Government entomologist of Ceylon, is bringing out a magnificent work on the scale insects of that island; but he finds insufficient support, and it is divulging no secret to say that the publication of this useful book will involve him in very serious financial loss. There is no properly classified national collection of scale insects (the only good collection in England is that of Mr. Newstead at Liverpool), and we are still totally ignorant of the coccid fauna of many colonies. The reasons for regretting this condition of affairs are mainly two:—(1) because in ignorance pests of this group are continually being carried to new regions, where they are liable to become destructive; and (2) because man is so mixing up the distribution of these insects that every year makes it more difficult to ascertain their natural habitats. Having regard for the experiences of the past, it is surely safe to say that the annual expenditure of a few hundred pounds in the investigation of these pests would be far more than repaid in economic as well as scientific gains.

T. D. A. COCKERELL.

University of Colorado, U.S.A., August 10.

A Parasite of the House-fly.

I SHOULD like to direct attention to an interesting parasite of the house-fly which is in this district extremely abundant this summer. The creature is, as a rule, very hard to find, and many thousands of flies may be caught in ordinary seasons without a single parasite being found upon them. The animal in question is one of the *Pseudo-Scorpionides* (? Chelifer), easily recognisable by its pair of long chelæ, and I should be glad if any of your readers would inform me to what genus it belongs and whether it is equally abundant this year in other places.

Eton, August 19.

M. D. HILL.

[1] In my original description, it is stated that the skin is not reticulated. The new material shows that it is minutely reticulated or tessellate in the middle of the back. The antennæ, described as 8-jointed, vary to 7-jointed, with the fourth joint longest, but the third nearly as long.

MORE LIGHT ON ANCIENT BRITAIN.[1]

IT is gratifying, and at the same time puzzling, to find that the antiquities discovered in part of a single county can provide material for two such voluminous works as Canon Greenwell's "British Barrows" of 1877 and the record of Mr. Mortimer's researches, now issued with the assistance of Mr. Sheppard, the energetic curator of the Hull Municipal Museum. The district investigated lies between York and Bridlington, and teems with relics of the past, most of the barrows, or burial mounds, dating from the Bronze Age, but two or three cemeteries containing Anglo-Saxon graves at least a thousand years later. The excavations in which the author has been concerned for so many years are well described; but those without special knowledge of the period will turn with most satisfaction to the introduction, where, with the aid of copious extracts from the earlier work already mentioned, some interesting generalisations are made from the data furnished by the spade. Evidence is brought forward in favour of cannibalism among the ancient Britons, a practice that has been suspected for some time; and human sacrifice, perhaps also suttee, seems to have been indulged in at the burial of an important personage. In some barrows there were signs that a circular hut or a pit-dwelling had been used as a sepulchre, the walls and roof being thrown down over the body; and the author's suggestion as to the

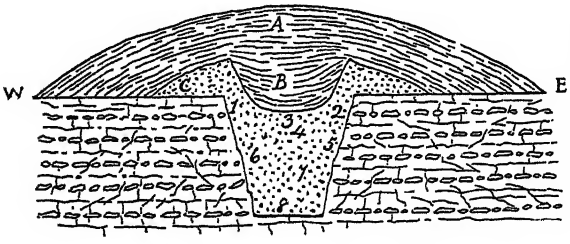

FIG. 1.—Section of Round Barrow, Aldro, E.R. Yorks.

origin of the incomplete ring formed by stones or a trench round many burials of the period is certainly plausible. In his own words, "these rings are probably marks of taboo or enclosures which were made at the beginning of the ceremony to mark off and protect the sacred spot in which the ceremony and interment were afterwards to be conducted, and the break in the circle had no other significance than to serve as a place of ingress and egress during the performance of the obsequies."

It is interesting to have existing evidence as to the sepulchral pottery confirmed by further discoveries. With a few very doubtful exceptions the so-called "drinking-cup" is never found with calcined human bones, and generally accompanies the primary, or at least one of the earliest burials, in the mound or the grave beneath it. Of the "food-vessels," 43 were found with cremations and 119 with unburnt skeletons; and these figures agree with Canon Greenwell's, giving a proportion of about one to three. Though occasionally found on the top of calcined bones, the cinerary urns, as their name implies, were generally used to contain the ashes of the dead, and "incense-cups" are invariably associated with the rite of cremation, though we must contest the statement that the latter vessels are also found in Scandinavia, Germany, France, and even the Troad.

The intricacies of the text are considerably simplified by numerous diagrams, giving the plan and vertical section of the barrow under examination, and a specimen is here reproduced to show how it is possible to read the history of a burial mound. One in the Aldro group measuring 84 feet in diameter and 5 feet in height was excavated in 1866. The clay and soil forming the upper part is marked A, while B is a boat-shaped mass of clay and soil below it, C being the chalk filling of the inner mound and grave below the original surface-level EW. Nos. 1–8 are interments of children and adults in a pit cut rather deeper than usual in the chalk rock; but they were not all complete skeletons, No. 7, for instance, being a heap containing a "drinking-cup" in 48 pieces, fragments of six human lower-jaws, and a number of small bones packed in an adult calvarium. Whether contemporary or not, these burials had been surmounted by a dome of chalk which was cut into for another burial at some later date and subsequently covered with the outer mound.

Of the succeeding Early Age of iron remains are few in this particular district, though abundant a few miles further north; but one burial of importance must be noted. The swords here illustrated were found with a skeleton, and belong to two distinct types; the longer is of usual dimensions and has the characteristic curved scabbard-mouth and the chape of the middle period of La Tène, while the shorter sword is the only one of the kind known to have been found in this country, and with similar examples from France and Switzerland may date from about 100 B.C. The human head between the branches of the pommel is evolved from the knob that appears in that position on certain short swords from the Hallstatt cemetery.

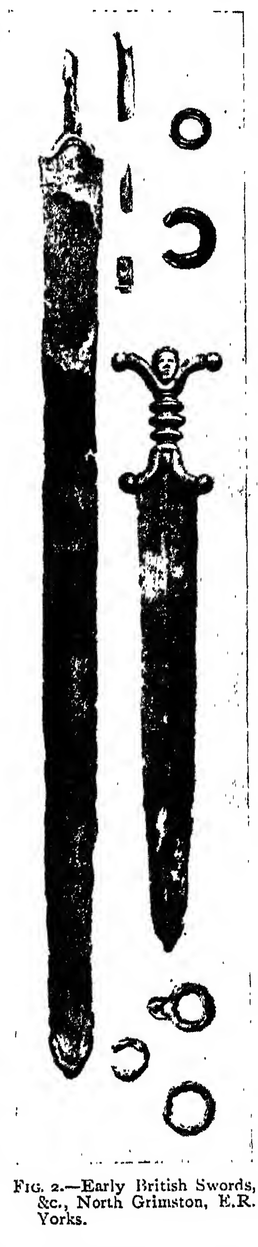

FIG. 2.—Early British Swords, &c., North Grimston, E.R. Yorks.

The Anglo-Saxon cemeteries contain unburnt bodies of which the orientation is instructive, while many excellent brooches and other relics have been recovered. These and the vast Bronze Age series have been amply and creditably illustrated, but, ungallant as it may appear, a protest must be lodged against the frontispiece, which gives a totally false impression of the Grimthorpe sword. In a work containing so many references misprints are excusable, but some are irritating; thus, Inverary (p. 361)

[1] "Forty Years' Researches in British and Saxon Burial Mounds of East Yorkshire." By J. R. Mortimer. Illustrated by Agnes Mortimer. Pp. lxxxvi+452. (Hull: A. Brown and Sons, Ltd., 1905.)

should be Inverury, and the next page has a cruel mutilation of Le Gros Guignon, while the reference to *Archaeological Journal* on the page before should be to the York volume (1848).

Following an excellent example, Mr. Mortimer furnishes relic-tables with all necessary details at the end of the volume, together with a copious index. Comparison with Canon Greenwell's table shows a very large proportion of primary interments, there being in one case as many as seventeen, to three secondary; but in a matter of this kind different conclusions might be drawn from the same data. Altogether the work is most welcome as a fund of material for more general treatment, and should encourage the study and publication of prehistoric finds in England.

THE FORTHCOMING TOTAL SOLAR ECLIPSE.

BY the time that NATURE appears next week, the total solar eclipse of August 30 will have become an event of the past, and we hope then to be in a position to announce that the careful preparations, which have occupied the minds of astronomers for so many months past, have been crowned with success.

Since the appearance of Dr. Lockyer's article concerning the eclipse, in our issue of February 23, several important modifications in the proposed arrangements have been made, but most of the eclipse observers are now at their stations erecting or adjusting their instruments for the final scene on Wednesday next. How much depends on the nicety of these adjustments can only be understood by those intimately concerned; but when it is recalled that since the general introduction of photographic methods into eclipse work the sun has only been eclipsed for about half an hour, that the duration of totality in the coming event exceeds 3¾ minutes, and that no favourable opportunity will occur again until 1912, when totality will only last for about 60 seconds, some idea may be obtained of the anxiety of those observers who are fortunate enough to take an active part in next Wednesday's observations.

Subjoined to this article is a letter from Dr. W. J. S. Lockyer describing the preliminary operations of the eclipse expedition of the Solar Physics Observatory, under the personal direction of Sir Norman Lockyer, K.C.B. When all arrangements for this expedition were nearly completed, but before Sir Norman Lockyer left England, it was decided by the French Government, in quite a friendly spirit, that the presence of a foreign man-of-war in Philippeville harbour was not desirable at the present time; therefore arrangements were made with the Spanish authorities, who rendered such valuable help to the similar expedition in 1900, for the party to go to Palma. Some of the work contemplated at Palma is described by Dr. Lockyer in his letter.

Some novel observations will be made by other observers. In a recent communication to the British Astronomical Association Mr. C. E. Stromeyer pointed out that geodesy might be assisted by an accurate determination of the path of totality. This path has been computed on the assumption that the earth has a certain form, and if the computed values are found to be incorrect, the errors in the assumption might be discovered. Another valuable suggestion was made in a letter from Dr. Johnstone Stoney which appeared in these columns on July 13, wherein the writer pointed out that the planet Mercury will be very near to a line joining the earth and the sun, and will therefore present a very thin crescent to the observer's view. If Mercury has an atmosphere, the horns of the crescent should appear prolonged by atmospheric refraction, and a careful observer, suitably equipped, should be able to detect the prolongation, and possibly to observe the spectrum of the tips.

M. Touchet suggests that the moon might be observed, both before the first and after the fourth contacts, projected on the brighter portions of the lower corona, by an observer employing a suitable dark glass with a small telescope.

In a brochure recently received from Señor Horacio Bentabol, of Madrid, the author makes a number of suggestions to eclipse observers by which the existence of a lunar atmosphere might be detected. Among other matters he suggests that delicate thermometric observations made for some hours before and after the eclipse might exhibit a heat-absorption effect due to the interposition of the lunar atmosphere, between the sun and the observer, before the actual body of the moon was interposed. Solar radiation observations might also exhibit the same effect. Photometric observations of the illumination of the sky might show an analogous absorption of light, due to the lunar atmosphere. Exact determinations of the solar diameter would, if the moon possesses an atmosphere, probably show the results of the refraction due to that atmosphere. The apparent hourly movement of the sun should become modified, as the lunar atmosphere is interposed, for the same reason. Many other points whereby the existence of such an atmosphere might be tested are given by Señor Bentabol.

As recently mentioned in these columns, French astronomy will be well represented at the various stations, whilst American astronomers have journeyed to a number of widely separated stations. Three expeditions have been sent from the Lick Observatory to Labrador, Spain, and Egypt respectively. At each station a search is to be made for an intra-Mercurial planet, and large-scale coronagraphs of exactly similar construction are to be employed. Should any actual movements take place in the corona during the two and a half hours which elapse between totality at Labrador and at Assouan, the photographs obtained at these respective stations should show it.

The Canadian Government has dispatched an expedition to Labrador, and has officially invited Mr. and Mrs. E. W. Maunder to accompany the same. Mrs. Maunder will employ a coronagraph exactly similar to that which Prof. Turner is using in Egypt.

The details concerning the regions crossed by the eclipse track, and the times of totality, &c., have already been given in many places, but the subjoined table giving the times and magnitude of the greatest phase in these islands may be of interest:—

	Eclipse begins d. h. m.	Greatest eclipse d. h. m.	Eclipse ends d. h. m.	Mag.
Greenwich	29 23 49	30 1 4	30 2 15	0·786
Edinburgh	29 23 44	30 0 55	30 2 4	0·724
Dublin	29 23 39	30 0 53	30 2 5	0·799

In the above table, which is taken from the *Companion to the Observatory*, the times are Greenwich Mean Time, which is reckoned from the previous mean noon, and the magnitude is given with the sun's whole diameter as unity.

The Solar Physics Observatory Eclipse Expedition.

Palma, August 18.

We have now been at Palma a week to-day, and are all thoroughly settled down, not only at the very excellent hotel in which we are located, but at the eclipse camp, which lies about a mile towards the north-west. We are a large party. There are

150 volunteers from H.M.S. *Venus*, including the captain and all the officers, and we ourselves total six, namely, Sir Norman Lockyer, Mr. C. P. Butler and myself, and three volunteer observers, Lady Lockyer, Mr. Howard Payn, and Mr. Frank McClean.

We arrived here on the morning of August 10, having transhipped at Gibraltar to H.M.S. *Venus* about noon on August 8. The arrangements for transferring the 110 packing cases from ship to ship were all that could be desired, an Admiralty lighter and tug being in readiness on our arrival. By five o'clock in the afternoon we were steaming away towards our destination, leaving behind us that great pile of rock, which eventually became a dim speck on the horizon.

Needless to say, the conversations in the captain's cabin, in the wardroom, and in many other parts of the ship were concentrated on eclipse matters, and this culminated in a lecture which I was requested to give to the whole available ship's company. The keenness displayed was universal, and the following day volunteers were called for to assist in the work for the eclipse, and, as I have previously mentioned, they now total 150. The same evening Sir Norman Lockyer gave a lecture, which increased, if possible, the keenness previously displayed.

On our arrival at Palma, which, by the way, is situated in a beautiful bay with an excellent anchorage, the ship was boarded by numerous officials after the customary salutes had been exchanged between the ship and the fort. Amongst those who came on board was our friend Mr. Howard Payn, who had preceded us in order to fix on a suitable site for our camp, to arrange for local labour and material, and to smooth things generally for us. The very admirable way in which this difficult and delicate task was accomplished by him in conjunction with Mr. Roberts, the British Consul at Barcelona, could not be surpassed, and all the members of the expedition are unanimous in singing their praises. For the expedition to Spain in 1900 Mr. Payn rendered a similar service, and on that occasion the arrangements he made were all that could be desired.

On the afternoon of our arrival at Palma, Sir Norman Lockyer and Captain Eyres, in the company of the British Vice-Consul, Mr. Bosch, paid some official visits, and afterwards the site selected by Mr. Payn was visited. This site is an ideal spot for a large eclipse camp, being sufficiently close to a landing stage for boats, walled in, and perfectly open for astronomical observations in all directions. The ground, which is private property, has been kindly lent by the owner for the purposes of the eclipse observations, and the members of the expedition are extremely grateful for the use of such an admirable camping locality.

Indeed, kindness itself has been displayed in every direction. All the authorities of the island have laid themselves out to supply anything that is required, and already these offers have been accepted in several ways.

On the early morning of August 11 work at the camp began in earnest. The tents, loaned to us by the War Office, were taken ashore and erected, and later in the day the packing cases were landed and carried by carts to the ground. Parties from the ship soon began to be acquainted with the contents of the cases they had so delicately handled, and by the evening the large wooden structure composing the dark room and the camera end of the prismatic reflector, and also the siderostats and cœlostat huts, were nearly all erected and covered. While this work was in progress, meridian lines were being pegged out and the positions for the concrete pillars fixed.

The erection of the piers for the instruments commenced on the following day, and so soon as these were completed the instruments which were to be placed on them were put together and set up.

At the time of writing (August 18, 10 p.m.) great progress has been made; most of the instruments are nearly erected, some are in approximate adjustment, while they are now all under canvas, the coverings having been set up in truly nautical style.

To gain some idea of the work undertaken, it may be mentioned that the larger instruments include a prismatic reflector of 76 feet focal length, a 6-inch three-prism prismatic camera, two coronagraphs (one 16 feet focal length) and an objective grating camera worked in connection with one cœlostat, a triple camera of 3-inch aperture and 12 feet focal length for photographing the eclipsed sun in colours, and a $3\frac{1}{2}$-inch coronagraph worked equatorially. Already each instrument has a party from the ship to assist in working it efficiently, and these are daily in the camp to render aid when necessary.

In addition to the above-mentioned assistants for the instruments, there are several other pieces of work which are being taken in hand. Thus the disc party has already erected discs of various sizes on imposing structures on the east side of the ground. Further, there are groups of observers for sketching the corona without discs, making star observations, recording the colours of the corona and landscape, observing the shadow-bands and sweep of the shadow, making meteorological observations, &c.

These and other parties are daily being drilled to render them as efficient as possible, and there is every hope that eclipse day will find them skilled and accurate observers.

We are, however, rather doubtful as to the kind of weather that will be experienced here on the eventful day. So far, the chances have been in our favour, but partially clouded skies are more common than one would like to see. A sharp thunderstorm broke over the town on the early morning of August 17, and rain fell in torrents. Fortunately there was no wind, and no damage was done. Those acquainted with the local weather conditions cheer us up by forecasting fine weather, but clouds are far more frequent than one would wish them, and the prospects are not nearly so good as they were in India in 1898 or Spain in 1900. In less than a fortnight's time our fate will be sealed.

In addition to our party, numerous other observers of different nationalities are taking or have taken up their stations in the neighbourhood of the town.

WILLIAM J. S. LOCKYER.

FIRST INTERNATIONAL CONGRESS OF ANATOMISTS.

THE first meeting of the Congrès fédératif international d'Anatomie was held in Geneva, and commenced on the morning of Sunday, August 6, by the opening of an exhibition of specimens and appliances illustrating recent progress in anatomy. The congress closed on the evening of Thursday, August 10, when three hundred members and adherents of the congress were entertained by the city of Geneva to an official banquet. The congress represented a conjoint meeting of the five leading anatomical societies—the Anatomical Society of Great Britain and Ireland, Anatomische Gesellschaft, Association des Anatomistes, Association of American Anatomists, and the Unione Zooligica Italiana. Almost every country was represented. Switzerland itself contributed more than 100 members, France 66, Germany and Austria 36, Great Britain

and Colonies 23, Italy 11, America 3, and other countries 16. The largest contributors to the proceedings of the congress, however, were the Germans; out of a total of 117 communications, 32 were made by them, 31 by the French, 18 by the British, 15 by the Swiss, 8 by Italians, 5 by Swedes, and 2 by Americans.

From every point of view the congress was a success. Anatomy is peculiarly susceptible of international treatment, the subjects for description and discussion being concrete and capable of direct demonstration. The language difficulty certainly hindered a free discussion on more than one occasion; for instance, on the second day, a speaker, after giving his communication in French, listened most attentively to a vigorous criticism in German, and, bowing profoundly, replied, "Je ne comprends pas l'allemand." With an agenda list overloaded with 117 communications, there was a grave risk of disorganisation. Thanks to the complete arrangements made by the committee of organisation, presided over by Prof. A. Êternod, of Geneva, and to the perfect arrangement of business by the president of the secrétariat, Prof. von Bardeleben, the proceedings of the congress made an even and steady progress. The success of the congress must also be ascribed to Prof. Nicholas, of Nancy, secretary of the French society; English members were indebted to Prof. Symington, president of the British society, and to Dr. Christopher Addison, its secretary. Each day's work was divided into two parts; the morning was devoted to papers, ten minutes being allowed for each communication, and three minutes to any member who wished to criticise; the afternoon was set aside for exhibition of new specimens and demonstrations of the material on which the communications of the morning were based, and this was by far the most instructive and profitable part of the day's work. The Swiss cow-bell, employed by the president of each day's proceedings (for the president of each society acted in turn as chairman) to warn the speaker that he had reached the limit of his allotted time, bound the members of the congress by a common sense of humour and materially aided the success of the meeting. In spite of the *entente cordiale*, the British anatomists associated more closely with the German than with the French members of the congress—an association determined, for the greater part, by the fact that the Germans were the superior linguists.

With so extensive a programme, it is impossible in a report such as this to do more than note the more outstanding communications. Making every allowance for prejudice of race, the first place, both in importance of results and excellence of technique, must be assigned to the contributions made by Prof. J. T. Wilson, of Sydney University, who placed before the congress the results of a prolonged investigation into the developmental history of ornithorhynchus made by his colleague and collaborator, J. P. Hill, and by himself. With the material now at their command they will be able to write a full and precise account of the development of the monotremes and throw a great deal of light on mammalian morphology. The photograph of an ornithorhynchus egg, in the eight blastomere stage, was shown. Most remarkable of all were the specimens and photographs showing the early developmental phases of the central nervous system. The medullary plates, instead of folding over at an early date to form the neural tube as in mammals generally, remain exposed on the surface of the embryo and thus give a superb opportunity of studying the processes of segmentation and differentiation of the central nervous system. The cephalic part of the central nervous system is seen at first not to be differentiated into three parts, viz., hind-, mid-, and fore-brain, but into two, a hind part, or archencephalon, and a fore part, or deuterencephalon, under which the notochord terminates. The archencephalon shows four or five sharply demarcated neuromeres in front of the neuromere connected with the facial nerve (prefacial neuromeres), but Prof. Wilson detects in some of them traces of a subdivision. There are three post-facial neuromeres. By using embryos of Perameles and Dasyurus to supply blanks in the ornithorhynchus series, Wilson and Hill were able to show that the neural crest forms at first a continuous hem on the lateral margins of the medullary plates. That part of the neural crest corresponding to the prefacial neuromeres undergoes, relatively to the rest of the neural system, an enormous growth forming a plate of cells which was mistaken by Selenka in other marsupial embryos for a mass of mesoblast. The neural crest connected with the facial segment forms the acoustic ganglion; that with the post-facial neuromeres the glosso-vagal ganglion, the rest of the crest becoming differentiated into spinal ganglia.

It is within the memory of even the younger zoologists that ornithorhynchus was regarded at one time as a toothless mammal; then came the discovery by Poulton and by Stewart that teeth were present but remained embedded in the gums. Prof. Wilson was able to demonstrate in his series of embryos the presence of two dentitions—the development and absorption of a milk dentition and the formation of a permanent dentition—that discovered by Poulton and Stewart. Thus ornithorhynchus, so far as its dentition is concerned, takes its place with diphyodont mammals. Further, it was shown that each cusp of the permanent molars is preceded by a separate milk tooth—a powerful argument in favour of the evolution of molar teeth by the concrescence of single-cusped teeth. Photographs were exhibited of a reconstructed model of the skull of a fœtal ornithorhynchus which shows many aberrant and puzzling features. Other contributions to the embryology of monotremes were made by Prof. Keibel, of Freiburg (models showing the development of the urogenital apparatus of echidna), and to the embryology of marsupials by Dr. Für Bresslau, of Strassburg (preparations showing the development of the pouch of *Didelphys marsupialis*).

Two papers on the agenda list, one by Prof. von Bardeleben, of Jena, entitled, "Die Homologie des Unterkiefers in der Wirbeltierreihe," the other by Prof. Gaupp, of Freiburg, "Die Nicht-Homologie des Unterkiefers in der Wirbeltierreihe," brought again into prominence that much-debated problem—the origin and nature of the mammalian lower jaw. Bardeleben maintained that the lower jaw of a mammal was strictly the same structure as that of a reptile, and produced, as evidence of his contention, mandibles of marsupials and of human fœtuses in which there could be traced lines somewhat similar to the sutural lines to be seen in the reptilian mandible. Prof. Gaupp's paper was a clear and vigorous denial of Bardeleben's contentions. In Gaupp's opinion the temporo-maxillary joint of mammals was a new joint formed between the coronoid process of the reptilian jaw and the squamosal, and quite different from the mandibulo-quadrate joint of reptiles. His conclusions were largely based on a consideration of the relationship of muscles and nerves to these joints. The new mammalian joint was formed in the insertion of the pterygoideus externus, the end tendon of which be-

came the interarticular disc, as can be seen in echidna. By means of a model he demonstrated the manner in which a new joint could be developed without leading to a disturbance of the function of mastication, thus leaving the quadrate to form one of the auditory ossicles (hammer). It must be admitted that Gaupp's theory explains the embryological phenomena, and clearly met with general acceptance by the members of the congress. Prof. Eugen Fischer, of Freiburg, pointed out that the theory explained the presence of cartilage which he had found in the developing coronoid and condylar processes of the jaw in the mole and apes. A model of an early developmental stage of the human mandible was shown by Dr. Alexander Low, of Aberdeen, who also demonstrated a special formation of cartilage, independent of Meckels, in the condylar and coronoid processes of the human jaw—facts in favour of Gaupp's hypothesis. In the opinion of the writer of this report, this vexed question is not yet settled, nor is it likely to be so long as anatomists seek to derive the mammalian from the reptilian type of mandible.

Ten communications dealt with the structure or development of nerve cells. One of these was a paper by Prof. A. Donaggio, of Naples, "Il reticolo neurofibrillare della cellule nervosa dei Vertebrata (con demostrazione di preparati microscopici)," which revealed the energy and fire which Continental anatomists can throw into their work. Prof. Ramon y Cajal, of Madrid, also brought to the congress specimens to demonstrate the direct continuity of the neuro-fibrillar network of the nerve cell with the dendrites on the one hand and the axon on the other. He had placed his microscopes and specimens on a window-ledge of a passage leading to the laboratory where Donaggio gave an enthusiastic demonstration to an intent circle of listeners. Cajal suddenly joined the circle and gave a direct contradiction to some statement of Donaggio. A lively scene followed; Cajal fetched his microscopes and specimens one by one from the passage and placed them impetuously before Donaggio. It was hard to ascertain the exact point in dispute, but it was subsequently discovered that it was a matter of thickness of section, Cajal maintaining that Donaggio's sections were too thin to demonstrate the relations of the neuro-fibrillar network of the nerve cell, while, of course, Donaggio regarded those of his opponent as too thick. The dispute was amicably settled by the discovery that both meant the same thing, namely, that the neuro-fibrillar network of the nerve cell was directly continuous with dendrites and axon.

The question of the development and regeneration of nerve cells again came up for discussion. Dr. John Cameron showed excellent photomicrographs of the developing optic and spinal nerve fibres in amphibians and birds which he believed to be both of central and peripheral origin. Optic fibres he regarded as direct prolongations from the nuclei of the retinal ganglion cells. Specimens were shown by Dr. Alfred Kohn, of Prague, demonstrating that the cells which go to the formation of a nerve, both fibre and sheath, are derived from the central nervous system—a histological confirmation of Harrison's clever experiment. Prof. Barfurth, of Rostock, produced the results of experiments on regeneration of nerve fibres made by C. F. Walter, and concluded that the axis cylinders could be produced by the cells of the nerve sheath.

Dr. George Streeter exhibited a series of models showing the development of the acoustic ganglion in human embryos. The cochlear ganglion is separated from the vestibular ganglion during development, and the association of the cochlear nerve with the nerve to the posterior ampulla is merely fortuitous; Dr. Giuseppe Levi, of Florence, gave an account of the various forms of cells found in the ganglia of the spinal nerves in developing pigeons. In another communication this author showed that ganglion cells vary in size with the size of the animal in which they occur; other cells are not affected by the size of the animal. Dr. E. B. Jamieson exhibited an excellent series of dissections of the brain, showing how various nerve tracts, usually seen only in section, can be demonstrated in their complete extent by means of scalpel and forceps.

Several contributions were made to our knowledge of blood corpuscles. Dr. T. H. Bryce gave an account of the development of the thymus gland in Lepidosiren, and showed that leucocytes were present before this gland was developed, and that, therefore, Beard's theory of the thymus being the primary source of leucocytes could not be entertained. Weidenreich, of Strassburg, traced the origin of all forms of white blood corpuscles from a common mononuclear cell, which was similar to, if not identical with, connective tissue corpuscles. With this conclusion Dr. Bryce agreed. Prof. Jolly, of Paris, described the formation of the mammalian red blood corpuscle by the gradual absorption and disappearance of the nucleus, not by an extrusion as is usually supposed. A research into the changes in the thymus gland which take place with age led Prof. Hammar, of Upsala, to conclude that the lymphoid tissue of that gland reached its maximum development in the years of puberty. Analogous results were obtained by Dr. R. J. A. Berry and Dr. Lack, of Edinburgh, regarding the development of the lymphoid tissue of the vermiform appendix. Using the average number of lymphoid follicles seen in sections of the appendix as an index of the development of the lymphoid tissue, they concluded that the maximum number (7) was found about the twentieth year, every subsequent decade leading to a decrease in the number of follicles.

Very few of the papers dealt with the naked-eye structure of the human body, or had a direct bearing on the problems which interest the surgeon or clinician—a very remarkable fact when one considers that the vast majority of the members of the congress are teachers of medical students. To this limited group of communications may be assigned the paper by Prof. Symington on the relations of the deeper parts of the brain to the surface and Prof. Cunningham's further observations on the form of the stomach, with special reference to hour-glass stomach. Papers belonging to this section were given by Chaine, Ledouble, Broman, Delmas, Gilis, Steida, and Poirier.

Contributions to physical anthropology were also few in number. Dr. Wright, of Birmingham, dealt with the characters of the men buried in the round barrows of Yorkshire, and found that they were identical with the men obtained from prehistoric graves in the neighbourhood of Fribourg, Lussane, and Berne. Englishmen of to-day are rather longer-headed than the men who were buried in the round barrows of Yorkshire, a fact which Dr. Wright explained by the invasion and intermixture of the long-headed Scandinavians with the men of the round barrow age. Prof. Eugen Fischer dealt with the deposit of pigment beneath the conjunctiva. It occurs in mammals generally, and in all primates and races of men save Europeans, in whom the sub-conjunctival tissue is free from pigment except under certain pathological conditions.

Some very remarkable specimens—showing exqui-

site technique—of the maturation stages in the ovum of the bat were placed before the congress by Prof. van der Stricht. Equally fine specimens, showing the manner in which the zona radiata is formed round the ripening egg of the rabbit, were shown by Regaud and Petitjean, of Lyons University. Their specimens showed that the zona radiata of the ovum is fibrillar in structure, and that the fibrils are arranged in an inner and outer zone. The fibrils are formed in the intercellular protoplasm in which the cells of the Graafian follicle are embedded. It will be thus seen that the zona radiata is not formed from, but deposited on, the ovum. Prof. Êternod, of Geneva, dealt with the manner in which the human ovum becomes implanted in the uterus, and the subdivision of the archenteron into the cavity of the amnion, the neurenteric canal and alimentary tract.

If one may judge from the nature of several contributions to this congress, there is a decided tendency to break down the barriers that separate the methods of the anatomist from those of the physiologist. Three communications dealt with results obtained by experiment on living animals. Prof. Sano, of Antwerp, by removing groups of muscles from the limbs and studying the subsequent changes in the motor cells of the spinal cord, sought to determine the position of the various motor centres in the cord. Prof. Tricomi, of Messina, used a somewhat similar method in investigating the paths of auditory impulses.

The members of the congress took part in the dedication of a monument to the memory of Prof. Hermann Fol, who set sail from Havre in his yacht, *l'Aster,* in the spring of 1892 to investigate the fauna of the Mediterranean. From the day he sailed until now not a single trace has been discovered of ship or crew. The members of the congress were lavishly entertained by Madame Fol. The congress placed a wreath on the bust of the Swiss physiologist Servetus, who discovered the pulmonary circulation in the sixteenth century, and was burned at the stake by Calvin because, so it is said, he denied the existence of the Trinity. A wreath was placed by the British section of the congress on the spot where he was burned, this gracious act being prompted by Prof. Dixon, of Trinity College, Dublin.

The congress was a social as well as a scientific success. An invitation from American anatomists to meet at Boston in 1907 was declined, as it was felt that at least a space of five years should intervene between each congress. A permanent committee for the organisation of the next congress was formed by the nomination of five men, one from each of the five affiliated societies. It is intended to bring out a bulletin containing the proceedings and transactions of the congress, to which purpose part of the sum (11,000 francs) raised by subscription in Geneva to meet the expenses of the congress will be devoted. When it becomes the turn of London to entertain this congress, it will not be found an easy matter to attain the standard of hospitality which has been set by Geneva.

PROF. T. R. THALÉN.

By the death on July 27 at Upsala of Prof. Tobias Robert Thalén, Sweden has lost one of her most eminent physicists and teachers. He conducted investigations of great delicacy and value in the field of spectrum analysis, and was the assistant of A. J. Ångström in much of his work. He also furnished valuable contributions to the knowledge of terrestrial magnetism, and devised ingenious methods of searching for iron-ore deposits. Born at Köping on December 28, 1827, he matriculated at the University of Upsala in 1849, where he graduated as Doctor of Philosophy in 1854. In 1856 he became lecturer on astronomy, and from 1856 to 1859 travelling scholarships enabled him to study in England, France, and Germany. In 1861 he was appointed assistant professor of physics at Upsala, and from 1869 to 1870 he was professor of physics at the Stockholm Technical School. In 1873 he was appointed professor of mechanics at Upsala, and in the following year was transferred to the chair of physics. This professorship he held until 1896.

The principal memoirs written by him dealt with the determination of lines in the solar spectrum (1860), researches on the magnetic properties of iron (1861), on the Fraunhofer lines (1866), spectrum analysis (1866), determination of the wave-lengths of metallic lines (1868), terrestrial magnetic observations in Sweden in 1869–71 and 1872–1882, researches on the spectra of metalloids (1875), the search for magnetic iron ore deposits (1877), and on the arc spectrum of iron (1885).

Prof. Thalén's researches on the spectra of metals and metalloids won for him wide renown, and are recognised as classical contributions to spectrum analysis. Partly in conjunction with Ångström and partly by himself he produced accurate and elaborate maps showing the wave-lengths of the lines in the spectra of many elements. He also made a careful examination of the absorption bands of iodine vapour, and engaged himself on the difficult problem of determining and properly assigning the lines in the spectra of bodies of the yttrium and cerium groups. At the period when these papers appeared, precise measurements were needed to settle several fundamental questions in spectrum analysis, and the researches in which Prof. Thalén took part were of great assistance in this connection. The revised list of the lines in the arc spectrum of iron, published in a memoir presented to the Royal Society of Upsala in 1885, is still a standard work of reference wherever investigations in spectrum analysis are carried on.

The magnetometer invented by Prof. Thalén for searching for magnetic iron ore deposits greatly facilitated the work of prospecting, and there is not a single iron mine of any consequence in Sweden where this instrument has not been used. It was described in a paper read by Mr. B. H. Brough before the Iron and Steel Institute in 1887. In appreciation of the value of this instrument, in 1874 the Swedish Association of Ironmasters awarded Thalén a gold medal; and in 1884 he received the Rumford medal of the Royal Society for his spectroscopic researches. He was a member of the Swedish Academy of Sciences, and an honorary member of numerous scientific societies, both in Sweden and other countries.

THE SOUTH AFRICAN MEETING OF THE BRITISH ASSOCIATION.

The various sections of the British Association met at Cape Town for three days last week, when presidential addresses were delivered and reports and papers were read and discussed. We print two more of the presidential addresses this week, and, following our usual custom, shall give in subsequent numbers other addresses, as well as reports of the proceedings of the sections written by members attending the meeting in South Africa. It is only necessary now, therefore, to refer to matters of general interest connected with the meeting.

On August 17 a special graduation ceremony in

honour of the association was held at the City Hall. The degree of Doctor of Science was conferred upon:—Prof. G. H. Darwin, F.R.S.; Sir William Crookes, F.R.S.; Sir David Gill, K.C.B., F.R.S.; Prof. Porter, of Montreal; Prof. Davis, of Harvard University; Dr. Backlund, director of the Imperial Observatory, Pulkowa, Russia; Prof. Bohr, Copenhagen; Prof. Engler, Berlin; Prof. Kapteyn, Groningen University; Prof. Penck, Vienna; and Dr. Sjögren, Stockholm.

At the conclusion of the ceremony, the Vice-Chancellor, Sir John Buchanan, read the following telegram from the Prince of Wales, Chancellor of the university:—"I desire to offer my hearty welcome to the members of the British Association who to-day receive our honorary degrees.—GEORGE, Chancellor."

The members of the association arrived at Durban on Tuesday, and were publicly welcomed in the City Hall, the Mayor of Durban, who was in the chair, expressing his confidence that the meetings would prove beneficial to mankind by widening the boundaries of scientific knowledge and by inculcating a deeper interest in scientific research.

In returning thanks on behalf of the association, Prof. Darwin is reported by Reuter to have said:—

It was exactly seventy years since His Majesty's ship *Beagle*, engaged in an historical expedition, sighted the coast somewhere about the latitude of Natal. At that time Durban was only a small village in the interior, entirely in the hands of the Zulus. It was a fact not hitherto recorded anywhere that his father, who was on board the *Beagle*, was anxious that Captain Fitzroy should put him ashore in order that he might make his way on foot or on horseback, or as best he could, to Cape Town. But it came on to blow, and the *Beagle* was unable to send a boat ashore. He felt that the chances which his father had of reaching Cape Town alive were so slight that he might say his presence on the platform that day was the result of a puff of wind.

The annual report of the council for the year 1904–5 was presented to the general committee at Cape Town on August 15. It is devoted chiefly to a statement of what action has been taken in connection with a resolution from the committee of the section of mathematics and physics expressing the opinion that the organisation of a Central Meteorological Department for the British Empire would be of the highest benefit to the progress of meteorological science and its application to the economic problems of the various colonies and dependencies. The resolution was referred to a committee consisting of Dr. A. Buchan, Dr. H. R. Mill, Dr. Shaw, and the general officers, to consider and report thereon to the council; and the memorandum drawn up by the committee and approved by the council on March 3 is abridged below:—

There is at present no provision for the systematic treatment of the meteorology of the British dominions. Observations of various kinds are made in nearly all the British colonies and dependencies, and summaries of these observations are generally included in the respective official publications. India, Ceylon, Canada, the several States of Australia, New Zealand, Mauritius, the Cape of Good Hope, and the Transvaal have organised meteorological establishments and issue regular meteorological publications. Information with regard to the meteorology of the Crown colonies and protectorates is to be found in the Blue-books of the several dominions.

There is no provision for the coordination of the methods of observing, the instruments employed, or the presentation of results. The want of a satisfactory system of coordinating the observations from the several dominions is to be deplored from two points of view—the economic and the scientific.

From the economic point of view, it is eminently desirable that facilities should be given for the comparison of the climatic features of the regions available for settlement and the conditions which affect various industries. At present it is possible to obtain a certain amount of information for an individual colony by reference to colonial Blue-books, but the data are of very different orders of completeness; and to ascertain in which colonies specified climatic conditions are to be found would be a labour of such difficulty as to be practically prohibitive. The Board of Trade publish a certain number of tables of meteorological results among their colonial statistics, but something of a more comprehensive character is required. From the scientific point of view the regular issue of the meteorological data for the British colonies in a published and easily accessible form is urgently desired by meteorologists of all countries.

But there is another aspect from which the scientific treatment of meteorological data must be regarded as having an important bearing upon the economic interests of remote parts of the Empire. Sir John Eliot, in his address to the British Association meeting at Cambridge, pointed out how the study of the meteorological conditions of the Indian Ocean and the bordering countries had been already applied to problems affecting the economic conditions of India as depending upon the variation of the monsoon rainfall, and he gave reasons for believing that the further prosecution of the inquiry promises valuable results for India, Australia, South and East Africa, and other countries bordering on the Indian Ocean if provision were made for dealing with the meteorological problem in a comprehensive manner with reference to the Indian Ocean as a whole.

Similar reasoning may be held to apply also to other oceanic areas, in or on the border of which British colonies are situated. In this connection it should, perhaps, be mentioned that the control of the meteorological organisation of the British West Indies is already passing into the hands of the United States. As a result of Sir John Eliot's representation, the attention of the council of the British Association has been directed to the advantages likely to accrue from the organised study of the meteorological problems affecting various groups of British dominions.

It has been further pointed out that such organised study can be most effectively secured by the establishment of a central institution devoted to these objects. Such an institution ought to be in close connection with the Meteorological Office, which is itself in regular correspondence with the meteorological organisations of foreign countries as well as those of the self-governing colonies. The meteorology of the ocean has been an essential part of the work of the office from its establishment in 1854, and oceanic data must necessarily be appealed to for the effective study of the meteorology of the neighbouring land areas.

By way of summary, the objects of the suggested institution may be briefly stated to be:—

(1) To give any information that may be required to the Governments or other authorities of the British dominions as to instruments and methods to be adopted for an effective system of meteorological observations.

(2) To compile and publish periodical reports upon the climatic conditions of the various parts of the Empire upon a comparable plan. To form an accessible depository of information upon matters concerning the climates of the whole Empire, and to afford information upon those subjects to inquirers.

(3) To provide a scientific staff for the study of the general meteorological conditions which affect the weather in the various British dominions, and in particular to promote the formulation of meteorological laws, and to apply them to explain and ultimately to anticipate the occurrences of abnormal seasons.

A copy of this memorandum was forwarded to the Colonial Office, with a covering letter suggesting that the question might be moved by a deputation to the Secretary of State. In reply, Mr. Lyttelton said that, whilst sympathising with the object which the council had in view, he did not think that there would be any advantage in receiving a deputation until he was in possession of further information on the subject. In satisfaction of this request, the committee drafted

another memorandum dealing mainly with the object numbered 3 in the foregoing summary, because the services indicated under numbers 1 and 2 would be included incidentally in the development of number 3. This memorandum is as follows:—

The idea underlying the proposal is to deal with the general meteorological conditions of wider areas than those with which the various meteorological offices of the world have hitherto been regarded as being primarily concerned. The British Meteorological Office does indeed concern itself with the meteorology of the oceans from the point of view of shipping. In effect, the proposal is to utilise further the information already obtained at sea in conjunction with land observations for the investigation of the meteorology of large ocean areas in relation to that of the adjacent land areas, and from the point of view of the land population.

It is known, for example, that the meteorological conditions of India, Australia, South Africa, East Africa, and Egypt stand in close relation to those of the Indian Ocean, and the study of these relations promises very important results in connection with the prediction of the seasons. This investigation requires that the information shall be treated in a manner different from that now followed for the more immediate purpose of its application to the interests of shipping.

The meteorological phenomena which are regarded as demanding careful study, in the first instance, are the following:—

The conditions of favourable and unfavourable seasons in India.

The droughts of Australia and South Africa.

The conditions of favourable and unfavourable Nile floods.

With those would be associated the relation of the weather of the Mediterranean to the Indian cold weather anomalies, and the relation of the South Indian anticyclone to the Antarctic ice.

The larger part of the necessary land data for the investigation of these particular questions can probably be found in the publications of the meteorological organisations of India, Australia, South and East Africa, Egypt, Mauritius, Hong Kong, Singapore, or can be furnished directly by those organisations. They should be supplemented by observations contributed by certain foreign Governments. The marine data would have to be compiled from the documents collected from ships by the meteorological departments of this country and India. The further development of the collection of observations—more especially of marine data—might be necessary, in order to complete the investigation.

The use of the data would be, in the first instance, to obtain a survey of the sequence of the more general weather changes over the whole region under consideration. The first step in the operations therefore would be to consider the nature and extent of the data available for the purposes in view, and the form in which they should be compiled for study or for publication.

A corresponding inquiry for the Atlantic Ocean and the countries bordering upon it is equally desirable, and should be conducted concurrently in the interests of the British Isles and the American and West Indian colonies.

In order to carry out the proposal, something more than what would be generally understood by "a moderate addition to the staff of the Meteorological Office" is required. The proposal involves a scientific investigation of a very important character which could not be regarded as merely an incidental addition to the usual operations of the office. A man of suitable scientific attainments should be responsible for conducting it in consultation with, and under the general supervision of, the director of the Meteorological Office. It is desirable to mark the nature of the qualifications expected in the person to whom the work is entrusted by giving him the title of assistant director, and providing a salary of from 400*l.* to 600*l.* a year. It should be remembered also that the Meteorological Office could not find accommodation for the proposed additional staff without some addition to the space at present available.

It is estimated that the annual cost of the work would be 2000*l.*, rising in five years to 2500*l.*, made up as follows:—

	£		£
Salaries: Assistant Director	450	to	550
Scientific assistant, computers and clerical staff	1,050	to	1,300
Publications, printing and stationery ...	300	to	500
Incidental Expenses, office rent, &c. ...	200	to	150

The estimate is based on the supposition that the Meteorological Committee would be willing to undertake the general control of the department as a branch of the Meteorological Office.

It may be mentioned that the Government grant to the Meteorological Office at present stands at 15,300*l.* The cost of the marine department, as shown in the report of the Meteorological Council for 1903–4, is 1366*l.*, exclusive of office expenses, publications, &c.

The council, in approving this memorandum, has caused it to be conveyed under a covering letter to the Secretary of State for the Colonies.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY PROF. H. A. MIERS, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

IN opening the proceedings of Section C in its first visit to South Africa, and speaking first on behalf of those who are visitors, I think I may justly claim that to no Section of the British Association can this visit be more interesting or even more exciting than to us; we enter for the first time a country the geological features and history of which, and the mineral productions of which, have long aroused the keenest interest among European geologists and mineralogists.

We have followed the discoveries and discussions of South African writers; we have read your views and have become familiar with your terminology; we have heard the reports of those who have visited the country, either as travellers or with the special object of investigating its geological problems or mineral resources; and, indeed, ever since the Geological Society of London received the historic papers of Andrew Geddes Bain, the father of South African geology, many of the memoirs of your own geologists have been communicated to European societies and journals; we have looked from afar with yearning eyes upon this alluring country; and at length we have found ourselves upon its shores.

It has not been given to many of us to see those great pioneers of South African geology whose work was done in the days before amateurs and experts could come out for a few weeks or months to take a hurried survey of the country; but their enduring labours, which have laid the foundation of all subsequent work, are well known to us, and it is not necessary for me to do more than mention the familiar names of Bain, Wyley, Stow, Atherstone, Sutherland, and Dunn. Of these only the last named survives; but when one remembers that his maps of North Cape Colony and of Orange River Colony have served as the basis of the maps now in use, one is reminded how recent is the whole history of South African geology, and how much was achieved in so short a time by these early workers.

It is exactly one hundred years since John Barrow wrote the concluding words of his "Travels in South Africa" which first directed attention to the geology of this country; it is only fifty years since Bain sent home the manuscript of the classic papers to which I have already alluded.

Since their days many have been the scientific visitors to the country who have remained here for longer or shorter periods, whose works have made us familiar with its problems and have contributed to their solution; the names of Cohen, Draper, Exton, Gibson, Green, Griesbach, Passarge, Rubidge, Sawyer, Schenck, and Seeley recall some of the most substantial scientific work which has been done either by visitors or residents. Several others who, without visiting the country, have by their researches in Europe helped to unravel the problem of South African stratigraphy were enumerated by Dr.

Corstorphine in his interesting and exhaustive Presidential Address last year.

If we must regret that we never had the opportunity of seeing the great pioneers and the earlier workers, we may rejoice that we have been able to meet those who are now actively engaged in continuing their labours; the period of cursory visits and fragmentary essays is closing and the era of deliberate and systematic surveys is beginning; we now look for authoritative information to the Cape Survey inaugurated by Dr. Corstorphine in 1895 and so ably continued by his successor Mr. Rogers; to the Transvaal Survey begun by Dr. Molengraaff in 1897 and auspiciously revived under Mr. Kynaston; and to the Natal Survey which Mr. Anderson has so successfully directed since 1901. I hope that it will not be long before there is no part of South Africa outside the direct supervision of a systematic and well-ordered survey.

There is perhaps some danger lest in a developing country, where the commercial possibilities are prominently before all eyes, the immense importance of such surveys should be overlooked, and lest it should be thought that what appears to be purely scientific research may be left to take care of itself until the mineral wealth of the country has been explored. I cannot enter too emphatic a protest against such a view; how closely the two interests are knit together must be apparent to anyone who reflects that the nature and sequence of the more northerly formations which have yielded coal, diamonds, gold, and metalliferous deposits can only be studied in the light of the more intelligible geology of Cape Colony and Natal. It is, moreover, immensely to the advantage of South Africa that you have intimately connected with the mining industry geologists of such training as Doctors Corstorphine, Molengraaff, and Hatch, who have all gained valuable experience upon geological surveys.

I may now, perhaps, cease to speak merely as a representative of the visitors and identify myself more closely with the Section as a whole; for the most gratifying feature of this meeting is that it is not merely a visit of strangers who are enjoying your hospitality, but that with Section C of the British Association is fused Section B of the South African Association, so that for the time being we are all colleagues; and even such vexed questions as the correlation of the rocks of the Transvaal or of Rhodesia with those of the Cape, or the origin of Banket, or of Blue Ground, or the extension of the Main Reef Series (perhaps it is no longer necessary to include the problem of the Dwyka conglomerate) can be discussed by us on the spot as members of the same body inspired by the same earnest desire for truth.

I began these preliminary remarks by asking that I might be regarded as the spokesman of the visitors, and therefore represented myself as a geologist visiting the country for the first time. I must, however, make a frank confession. Not only is this my second visit to the country, but I have not even any claim to be called a geologist. My training and experience have been such that upon many of the questions which must be most interesting to this Section I am not competent to form an opinion or to appreciate properly the evidence. I must, therefore, crave your indulgence if in this Address I refrain from discussing any of the problems of surpassing interest which naturally engage the attention of those who are occupied with the study of South African geology. It would indeed be an impertinence for me to do so.

I venture, however, to hope that the frontier between geology and mineralogy is so ill-defined—if indeed a scientific frontier can be said to exist—that the thoughts and occupations of one who has confined himself to the study of minerals, and that rather in the laboratory than in the field, are not alien to the interests of Section C.

Experimental Geology.

A somewhat lamentable aspect of modern science is the vast array of unorganised facts which are awaiting coordination; this is too often because they have been amassed without any definite idea of the purpose which they may serve; consequently it may happen that laborious observations belonging to one science may fail to attract the regard of a neighbouring science merely for want of the mutual acquaintance which would make them serviceable to each other; and in these days of exclusive specialisation the introduction which might lead to a happy union is, perhaps, not brought about for years. None can be more fully alive to the importance of such an alliance than those whose work lies on the borderland between different sciences; the mineralogist, for example, is in contact on the one side with the experimental sciences of chemistry and physics, and on the other with geology, which has scarcely yet entered the experimental stage. He cannot fail to be impressed by the need of the appeal to experiment on the geological side of the border, and it is perhaps his duty to supply the want so far as lies in his power.

Owing to this very need some of the most difficult problems in geology are those concerned with the origin of minerals and of the rocks which they compose. One need but recall the many theories which have been held about the origin of mineral deposits, the filling of metalliferous veins, the local concentration of certain minerals, the distribution of various rock types, the existence of rock magmas of diverse compositions, and the differentiation of their constituents. Could the importance and difficulty of such problems be better illustrated than in South Africa, and by its two most valuable minerals, gold and diamond?

Now all these are problems in which direct appeal may, and indeed must, be made to laboratory experiments; the well-defined minerals of which the earth's crust consists do not, after all, number much more than 800, and of these many have already been manufactured in the laboratory. Speculation upon the origin of rocks and minerals should surely be controlled by the results of experiments, and equally should experiment which is to be of service to geology be guided by a knowledge of the problems to which it is to be applied. It will be my object in the present Address to illustrate these principles by examples drawn from recent experimental work which can be applied to geological problems, and to indicate the course which such research is likely to pursue in the immediate future.

It seems to be sometimes expected of a Presidential Address that it should contain a summary of the progress of a science during past years, and this is no doubt very useful and instructive; but if we are to go forward in our scientific work we must not be satisfied with the patient accumulation of details, or content to congratulate ourselves upon the number of them which have been amassed. I venture to think that it is more profitable to take our stand upon the actual work of to-day, and from that tower of observation to look forward to the future rather than backwards to the past; to exclaim with the poet—

> "No, at noonday in the bustle of man's work-time
> Greet the unseen with a cheer!
> Bid him forward."

It would be interesting enough to trace the history of the artificial reproduction of minerals, beginning with the famous experiment of James Hall; to follow the lines that led to the development of the French School during the last half of the nineteenth century; to dwell on the researches of Senarmont, Ebelmen, Daubrée, and Sainte-Claire Deville; to show how the increasing study of petrography and the invention of the electric furnace have led to renewed activity in the attempts to reproduce igneous rocks and the rock-forming minerals; to discuss the more modern experiments of Fouqué and Lévy, Lagorio, Loevinson-Lessing, and Morozewicz; or to describe the manufacture of many an interesting mineral by de Schulten and others who are actively prosecuting research of this nature, including such sensational achievements as the production of the ruby by Frémy and of the diamond by Moissan.

Instead, however, of attempting a survey of all that has been done, or even of all that is being done in the artificial reproduction of minerals, let me adhere to the principle that I have laid down, and discuss only a few of those researches, now being carried on, which promise to be most fruitful because their methods and aims are inspired by the discoveries and views of modern chemistry and modern physics.

Van 't Hoff's Work on the Salt Deposits.

Among such researches the most remarkable are those conducted by Prof. van 't Hoff and his pupils during the last eight years upon the Stassfurt salt deposits. These

deposits are of enormous extent, more than 1000 feet thick, and consist of fairly well-defined layers of various sulphates and chlorides of sodium, magnesium, and potassium, and their double salts and hydrates. It has long been supposed that the minerals have been derived from the evaporation of sea-water which contains in solution the chlorides of sodium, magnesium, and potassium, with sulphate of magnesium and small quantities of calcium salts; and the general sequence of the minerals is that of their solubility; the less soluble sodium chloride crystallised out first and is at the bottom, while the very soluble magnesium chlorides, having been the last to crystallise, occupy the top of the series. But the problem is by no means so simple as to be one of mere solubility in water; the rock salt itself persists through the whole series, and some of the associations are difficult to explain.

As is well known, the modern theories of solution mainly rest upon the behaviour of dilute solutions from which the principles of electrolytic dissociation have been deduced; but in the case of the concentrated solutions from which dissolved substances actually crystallise, very little is really known about the liquid itself. A great deal is known, however, about its equilibrium with the solids that separate from it, and the general laws of this equilibrium are expressed by the phase-rule deduced from mathematical considerations by Willard Gibbs, which states how many mechanically separable constituents can coexist under varying conditions of equilibrium in a system containing a definite number of chemical components.

A solution saturated with a given substance is one which is in equilibrium with that substance when the latter is in contact with it in the solid form; the phase-rule indicates the number of solids which must be in contact with a given solution; the only difficulty in practice is to determine the nature of the double salts or distinct hydrates that may be formed.

By means of a series of experiments upon the solubilities of these salts, either singly or in the presence of one another, in order to determine the composition of solutions saturated simultaneously with two or more substances, it is possible to obtain a graphic representation of all possible solutions containing the salts present in sea-water. From this the course of crystallisation of any particular solution, for example sea-water, can be predicted.

The general sequence thus theoretically predicted is as follows:—(1) Rock salt; (2) Rock salt with the magnesium sulphate, epsomite; (3) Rock salt with the double sulphate of potassium and magnesium, leonite; (4) Rock salt with leonite and the potassium chloride, kainite; (5) Rock salt, the magnesium sulphate kieserite, and the double chloride of potassium and magnesium, carnallite; (6) Rock salt, kieserite, carnallite, and the magnesium chloride, bischoffite. This last combination will persist until all the water is evaporated. This is found to be the general sequence, not only of the salts obtained on evaporating sea-water at 25°, but also of the Stassfurt deposits.

Up to this point the results have been summarised by Dr. E. F. Armstrong in a report presented to the British Association in 1901. Since that date the research has been prosecuted actively by van 't Hoff and his pupils, and now the conditions of equilibrium at 25° have been mapped out, not only for the above compounds, but also for the minerals thenardite, glaserite, astrakanite, and reichardtite, which occur in these deposits. The whole process of crystallisation of the solution, from which no fewer than twelve different salts have separated, can, therefore, be predicted, and their sequence and associations can be traced through numerous stages, beginning with the separation of rock salt and ending with a mixture of rock salt, kieserite, carnallite, and bischoffite.

In reconstructing the history of these deposits account must also be taken of the varying vapour pressures of the solutions which are saturated with the different compounds, as this really determines which particular compounds are stable, so that the matter is by no means so simple as might appear from this brief sketch. It is further necessary, in order to bring the process within reach of calculation, to assume that each deposit is removed from contact with the mother liquor after it has crystallised out; but fortunately this is practically what has happened in the Stassfurt deposits, for each layer is more or less separated from the succeeding one by an intervening layer of clayey material.

It may be possible even to go a stage further and obtain a clue to the actual temperatures that prevailed, for two minerals, langbeinite and löweite, are absent from the theoretical model made by van 't Hoff to represent what must happen during evaporation at 25°; and this indicates that while the deposits crystallised the temperature really rose higher than 25°, probably as high as 43°; in fact, after the conditions of equilibrium have been worked out, the appearance or disappearance of certain minerals can be used as a sort of geological thermometer, capable of indicating the limits within which the temperature can have varied.

The whole investigation is a splendid example of experimental research devoted to a particular problem and directed by a well-established theory; the chemist in his laboratory has now succeeded in tracing the changes that took place ages ago in the bed of a land-locked sea as it laid down its contents and finally became a dry basin, although he is not able to reproduce the original conditions or to work for the long periods which Nature had at her disposal. Without the logical consideration of the conditions necessary for equilibrium, countless experiments might be made upon these salts, and an immense amount of speculation might have been devoted to their possible reactions in the liquid state, about which we know so little, instead of to their equilibrium when solidifying, about which we know so much more.

Some Petrographical Problems.

The other geological problems which I have mentioned have also been beyond the reach of actual experiment, for it is hopeless to attain the immense pressures and high temperatures or the enormous time that may have been required for the growth of natural minerals in rocks and veins; and so when difficulties are encountered there is a tendency to "explain" them (if the word may be so misused) by reference to the mysterious effect of conditions which cannot be brought directly within the reach of experiment.

I cannot help thinking that this has to some extent occurred in the discussion of the petrographical problems which I propose to consider next. There are two great liquid reservoirs from which minerals have crystallised—the sea, with its dissolved salts, and the subterranean baths of molten silicates, from which the igneous rocks have been derived. It is true that in the sea two of the constituents, water and sodium chloride, largely predominated over the others; but, after all, both sea and lava are liquids subject to the same physical and chemical laws.

An admirable summary of the evolution of petrographical ideas was given in the Presidential Address to the Geological Society of London in 1901 by Dr. Teall, who dealt both with the consolidation of rocks from molten magmas and their differentiation into species. It is not, therefore, necessary for me to consider anything but recent work which has been done during the last four years, and the earlier controversies may be left out of account.

Among the many problems relating to the mineral and chemical constitution of rocks which have yet to be solved, two, and those perhaps the most important, should lend themselves most readily to experimental treatment. The first is the problem of rock differentiation: why does a magma, even one which has presumably crystallised *in situ*, separate itself into zones, or layers, or streaks of different constitution? And the second is the problem of mineral differentiation: why does a granite magma, for example, crystallise as a mixture of the particular minerals mica, felspar, and quartz, and why is the least fusible mineral the last to crystallise?

It will scarcely be possible for me to deal in this Address with more than the second of the two problems, but it will be apparent from the somewhat parallel case of the salt deposits that the mere order and manner of crystallisation of a mass of molten silicates must be a sufficiently complex problem to exhaust our attention for the present.

Magmatic Differentiation.

If we are to consider only recent experiments which have a bearing upon the problems of rock magmas, it is not necessary to say much about the first great petro-

graphical problem, that of the differentiation of magmas into various rock types; for in this connection very few experiments have been made, and practically none of recent date. Observations of the facts as they present themselves in the field accumulate every day; almost every important petrographical region is being studied with the particular object of determining the mutual relations of its rock masses and the factors which have contributed to their differentiation. They have been ably discussed by Becke, Brögger, Becker, Cole, Harker, Iddings, Judd, Lacroix, Lévy, Pirsson, Rosenbusch, Teall, Washington, Zirkel, and many others; appeal has been made to the action of gravity, of temperature differences, of diffusion, of electric currents, of fractional crystallisation, of re-fusion, of chemically combined water, of absorption of the country rock; but with the exception of a single case, observed in the glassworks of Targowek, in which the top of a molten glass was found to contain less lime and more silica than the bottom, and some observations by Doelter upon boron-glass, there is scarcely a single experiment upon silicates which really bears directly on the question. That artificial glasses are far from homogeneous is known to glass-workers and to makers of lenses, but there is nothing comparable with the splitting of a magma into two or three distinct liquids which solidify as different rocks.

It is in the case of laccolites that the problem ought to present itself in the simplest form, for we may regard them as basins of igneous rock which have been practically imprisoned within solid walls and have crystallised *in situ*. There can, I think, be no doubt that differentiation has generally taken place even in such basins, that the margins have often a different mineralogical and chemical constitution from the more central portion, and that the differences are greater than can be accounted for by solution of the enclosing rock, and are often of a chemical nature which cannot be so explained.

The various theories that have been propounded fall into two distinct classes—those which seek the cause in the separation of solid material from the liquid, so that when the latter subsequently crystallised it constituted a different rock from the former; and those theories which assume that different liquids have separated from each other and then solidified as different rocks.

The first conception satisfactorily explains the manner in which the least soluble minerals are concentrated at the bottom or margin of an igneous mass, for they naturally crystallise first where the mass is coolest, or where contact with other crystals may have occurred; or even if they have been precipitated as a cloud throughout the magma they must be carried about by convection currents and ultimately sink together unless the magma be very viscous. Most geologists will probably agree with the conclusions of Vogt that some of the most important deposits of metals, metallic oxides, and sulphides have been produced by magmatic differentiation from deep-seated magmas which now constitute basic rocks associated with them. But this does not explain how the mass which has crystallised out may be not a mineral but a rock.

The actual observations on crystallising solutions do not amount to much; it is quite clear from laboratory experiments that crystals do grow by means of convection currents, which produce a flow of stronger solution towards the crystal and of weaker and warmer solution upwards and away from the crystal. The concentration currents can easily be seen in any ordinary aqueous solution as streaks in the liquid. Again, that there might be a slight difference in the concentration of the upper and lower, or of the warmer and cooler parts of a solution has also been shown. That a very considerable difference in concentration can be produced by centrifugal action was proved only last year by the experiments of Calcar and de Bruyn, in which solutions contained in rapidly rotating vessels became more concentrated in the portions furthest from the axis of rotation.

Schweig has recently suggested that the crystals which fall to the bottom of a rock-magma may be unstable compounds, which re-dissolve when the pressure is relieved, and so give rise to an underlying magma of different chemical constitution.

Harker, also, some time ago, suggested the existence of horizontal layers of different liquid magmas above each other, thus attempting to explain the presence of quartz in basic rocks as due to the crystals which had sunk into the basic magma from a more acid magma floating upon it.

The second theory, that of liquid differentiation, regards such layers as actually produced by the spontaneous division of a magma into two liquids of different composition, and if it be tenable seems more capable of explaining the geological facts.

The experiments bearing on the subject are well known, and have been quoted by Bäckstrom and Teall; mixtures of phenol and water, or of aniline and water, which form a homogeneous solution above a certain temperature, may below that temperature (which is a sort of critical point of the solution) divide into two solutions, one consisting of phenol in excess of water, the other of water in excess of phenol; and these two solutions are not miscible, but separate into two distinct layers.

Many pairs of substances have now been found to exhibit this incomplete miscibility, which varies with the temperature and may at certain temperatures become complete; among them are some of the metals such as zinc, lead, bismuth, and silver.

If rock-magmas can really behave in this way, there is no difficulty in explaining their differentiation; but experiments upon fused silicates have not disclosed anything of the sort, though they are made far below the critical temperature.

The case of nicotine and water, which has recently been described by Hudson, is remarkable and suggestive: above a temperature of 205° a mixture in equal proportions is a clear liquid; at 205° it divides into a saturated solution of nicotine in water floating on a saturated solution of water in nicotine; at 90° these two layers change places; at 64° they mix again and the liquid becomes once more homogeneous.

It is, of course, possible that fused silicates at experimental temperatures correspond to nicotine and water below 64°, and that rock-magmas correspond to the same mixture at higher temperatures.

In discussing the reasons why in laccolites of the Square Butte type the margin should be more basic, and in laccolites of the Magnet Cove type more acid than the centre, Washington regards the magma as a mutual solution of an alumo-alkaline substance with a ferro-magnesian substance; whichever of these is in excess may be regarded as solvent, and crystallises first, for example, either the syenite or the shonkinite. In a laccolite where no differentiation has taken place, as in the Henry Mountains type, he supposes the mixture to be eutectic or such that they crystallise together. Pirsson, in a paper recently published upon the "Highwood Mountain Laccolites of Montana," while attributing a greater part in the process to the action of convection currents, also regards the ferro-magnesian minerals, taken together, as constituting the solvent and crystallising first as shonkinite.

In fact, stated quite baldly, these latest views tend to a compromise between the two theories which I have just mentioned. They regard the splitting of the magma as produced by a fractional crystallisation, only now the mass which crystallises is not a mineral but a rock; in other words, they assume that rocks may be dissolved in each other, and may crystallise from each other as though they were minerals.

In this matter of magmatic differentiation, then, there has been during the last few years a large accumulation of geological evidence, a little new speculation, but practically no new experimental work, and scarcely any progress.

Mineral Differentiation and Eutectics.

Let us pass to the second petrographical problem, that of mineral differentiation, the nature and order of the minerals which crystallise when a cooling magma becomes a solid rock mass.

It has been laid down by Rosenbusch, and is accepted as a general rule (in spite of many exceptions), that the order in which the various minerals crystallise is one of increasing acidity, ores and oxides and so-called accessory minerals first, then those minerals which are comparatively poor in silica, then those which are richer, and finally, if

it be present in excess. the silica itself. It has also been supposed that the order may be one of the fusibility of the various minerals under the conditions of their formation; the least fusible minerals being the earliest to crystallise, and the most fusible the latest. Interesting speculations concerning the melting point of quartz at high pressures, and its consequent order of crystallisation, have, for example, been published recently by Stromeyer and Cunningham.

It is not necessary, however, to regard the molten magma as a mere mixture of fused minerals which solidify more or less independently and consecutively; it is more reasonable to regard the whole magma as a solution in which the various minerals are dissolved, and from which they crystallise as it cools. Now the temperature at which a substance separates from solution is generally far below its melting point, and the order in which the constituents of a mixed solution will crystallise is the order of their solubility in it, and bears no direct relation to their fusibility or to their chemical composition.

Teall in 1901, after discussing the controversies and the evidence on which they are based, came to the conclusion that rock-magmas are solutions, and that the order in which the minerals consolidate depends upon the nature of the constituents and their properties, and is not by any means the order of their freezing points. As to the particular minerals which crystallise, he thought that the molecular grouping in the magma is determined by mass action and by the mutual affinities of the bases, the silica, and the alumina. Concerning future research he ventured to predict that the next advances were to be made by experiment controlled by the modern theory of solutions.

Thirteen years earlier Teall had himself contributed a valuable suggestion based upon Guthrie's work on cryohydrates. When a mixture of nitrate of lead and nitre is fused and allowed to cool, the constituent which is in excess will crystallise out as from a solvent until the proportions left in the liquid state are 47 of lead-nitrate to 53 of nitre, and this mixture will then solidify at 207°, not as a uniform compound, but as an intimate mixture of the two salts, the *eutectic,* which crystallises at the lowest possible temperature, and is the only mixture which has exactly the same composition as the liquid from which it solidifies. Teall made the illuminating suggestion that micropegmatite is an eutectic consisting of quartz and felspar, and represents in certain rocks the final mother-liquor from which the other minerals have crystallised out. Eutectics in metallic alloys have been much studied during recent years: in the Address of 1901 Teall was able to strengthen his case by showing that spherulitic and micropegmatitic structures found in obsidian and other acid rocks are paralleled by similar structures developed in eutectic alloys, according as they have been rapidly or slowly cooled.

In the following year appeared a theoretical paper by Meyerhoffer concerning the ideal case of a molten mixture of two substances, *a* and *b*, which do not suffer double decomposition, nor form a double salt, nor an isomorphous mixture.

Let a diagram be constructed, with temperatures as ordinates and composition of the magma as abscissæ, giving by a curve the nature of the magma which is in equilibrium with either solid *a* or solid *b*. The curve has the form of a V; one arm represents the temperature and constitution of the liquid which can be in equilibrium with *a*, and the other that of the liquid which can be in equilibrium with *b*; and the lowest point corresponds to the eutectic, which is in contact with both.

Let a point above the curve represent the temperature and constitution of the liquid magma containing excess of *b*; as the magma cools this point descends to the *b* branch and travels along it while *b* is crystallising out, until the eutectic point is reached, when *a* and *b* both crystallise out together at a temperature below the melting point of either. The order of crystallisation is therefore determined solely by the composition of the magna as compared with that of the eutectic. If, however, the liquid be cooled slowly, crystallisation may be postponed until it has become supersaturated with regard to one constituent or the other, or both; a state of affairs represented by a prolongation of the arms of the V below its lowest point, and then the order of the crystallisation may be inverted.

In a rock-magma there are of course many other factors to be taken into account as determining the order in which the minerals separate; for example, the formation of both double salts and isomorphous mixtures, the possible production of unstable solid compounds which may become converted into stable compounds or may be re-dissolved soon after they have come into existence; and also the relative velocities of crystallisation, changes of temperature and pressure, action of steam, &c.; but the principle laid down by Meyerhoffer must be that which controls the process.

It might be objected that on this hypothesis the consolidation of every rock-mass ought to terminate with an eutectic mixture, whereas this appears to be by no means the case; in fact, it is only among some acid rocks that structures much resembling the eutectic mixtures of alloys are to be found. On the other hand, if the conditions of cooling are such that the magma becomes supersaturated with one mineral after another, it will overshoot the eutectic composition before each crystallises, and the final consolidation may be a well-marked sequence instead of a simultaneous crystallisation.

The controversies which have raged concerning the classification of rocks and their nomenclature appear to me to contribute little to the real advancement of knowledge. There are, I think, two more profitable lines of research which should accompany each other. We may take the facts as we find them and endeavour to explain them by the known laws of solutions aided by the phase-rule, provided that we have good reason to believe that rock-magmas behave like solutions, and we may make experiments upon slags and fused silicates and ascertain how far they resemble natural rocks in their behaviour and their mineral constitution. Some of the workers in this field have been led to regard rock-magmas as undoubtedly similar to ordinary solutions; others hesitate to seek an explanation for their features in the laws which govern the solutions studied in the laboratory. The two views are represented in the persons of the two men whose names are most closely identified with recent experiments, Vogt of Christiania and Doelter of Graz.

Doelter's Work on Melting Points and Solubilities.

The labours of Doelter and his pupils have been largely devoted to the melting points of the rock-forming minerals and their solubility in silicate magmas. From experiments upon these minerals and their mixtures they have come to the conclusion that in many cases the melting point of the mixture is about the mean of the melting points of the constituents, and that in such cases, therefore, there is no evidence that the freezing point is lowered, or that an eutectic mixture is formed; so that it is not safe to apply the theory of cryo-hydrates to fused mixtures of silicates.

Doelter is therefore led to regard the silicate-magmas rather as mixtures of various constituents which may be dissolved in each other, but which are not by any means necessarily identical with the minerals which separate on cooling. The whole process seems to him to be far too complicated to be explained by any such simple principle as the mere relative proportions of the various constituents to each other and to their eutectic mixture; the order of crystallisation must be determined by a number of factors, such as temperature, velocity of crystallisation, the interval between the softening and fusing of each mineral (which he finds to be considerable), viscosity, capillarity, the presence of water and mineralising agents, and the absorption of adjacent rocks.

To choose a simple example: minerals such as zircon, corundum, and titanite separate for the most part early, because they are less soluble. On the other hand, magnetite is one of the more soluble minerals, and yet it is one of the first to separate; the same is to a certain extent true of augite, but not always. It is possible that in a magma which still contains the iron of the magnetite in solution plagioclase and augite may be comparatively soluble and magnetite comparatively insoluble, but that when magnetite has already crystallised out from the magma the plagioclase and augite may be comparatively

insoluble; the experiments which are wanted are experiments upon the solubility of certain minerals in magmas of known composition under known conditions; in these and similar instances the order of separation is that of the solubility, but such physical factors as the velocity of crystallisation (which varies very considerably with the temperature), and the viscosity, may completely invert the order.

Direct experiments made by Barus and Iddings upon the electric conductivity of silicate magmas afford evidence that such magmas contain dissociated as well as undissociated molecules, so that they cannot be regarded as merely fused mixtures of certain minerals. If two or more rock-forming minerals be fused together it may happen that they form new compounds and crystallise out as different minerals, or if one or the other remains unchanged it may crystallise out in a different proportion. All this shows that double decomposition goes on in the liquid. We cannot therefore expect, without knowing the degree of dissociation, to make much use of the lowering of the freezing point in order to calculate the other factors in the process of rock-formation.

Doelter concludes that upon the whole the normal order of crystallisation in rocks is in the main that laid down by Rosenbusch long ago, namely, an order of increasing acidity, but that it is determined by the mutual affinities of the molecules in the magma, and by the relative power of crystallisation of the components into which they unite themselves, and that the physical factors which I have already enumerated play a very important part in the process. No one has endeavoured more systematically than Doelter to determine for the rock-forming minerals the melting points and the solubilities, without which it is impossible to make much progress in our reconstruction of the history of rocks. He has recently shown us how the microscope may be used in the study of fused silicates at high temperatures, and has so opened up a new field of research.

Vogt's Applications of the Laws of Solutions.

The work of Vogt has extended over many years, and is now summarised in two remarkable memoirs recently published by him, in which are expressed his mature opinions upon silicate magmas; the reasoning is based upon his own experiments, upon those of Doelter, and upon the classic researches of Ebelmen. It is now generally conceded that the particular minerals produced in a silicate magma depend much more upon the chemical composition of the magma than upon temperature and pressure; Lagorio and Morozewicz were led to this conclusion by their own experiments upon fused silicates. Experiments upon slags at ordinary temperatures and pressures may, therefore, be invoked to elucidate the formation of rocks.

In 1902 Vogt stated his conviction that the laws of solutions may be applied to igneous rocks, and his two recent memoirs are, in fact, an attempt to explain the experiments upon slags and fused silicates as examples of the operation of these laws.

All important, according to him, is the composition of the eutectic mixture; he finds that if the analyses of silicate magmas be arranged according to their oxygen ratio or acidity, the various minerals of which they consist make their appearance within fairly well-defined limits. For example, in the case of the Ca-Mg-Fe-Mn slags, which contain little alumina, olivine and the melilite minerals only make their appearance in the more basic slags, and the metasilicates in the more acid, the limit between the two corresponding to an acidity of about 1·6.

The limit of individualisation between the various minerals is supposed to correspond to their eutectic mixture. Such slags may, therefore, be regarded as a mutual solution of two or more of the minerals olivine, enstatite, hypersthene, augite, the gehlenite-melilite group, akermanite, wollastonite, and the hexagonal metasilicate, which is so characteristic of the more acid slags. The particular minerals which make their appearance are practically determined by the acidity of the magma and by the relative proportion of the bases present, particularly by the ratio of the calcium to the magnesium-iron-manganese group; in other words, Vogt asserts that a silicate magma is a mutual solution of the various crystalline compounds that actually make their appearance as it solidifies, and that the order of crystallisation depends upon their proportion in the magma as compared with their proportion in the eutectic. The old conception of a solvent and a solute ceases to have much meaning; the matter which is of supreme importance is the nature of the eutectic mixture when the constituents are given; thus micropegmatite and microfelsite represent the eutectic of felspar and quartz, and correspond to a mixture of about 74 parts of felspar to 26 of quartz, as indeed has been stated by Teall.

Now, if we are justified in regarding rock-magmas and fused silicates as mutual solutions of certain definite compounds, and if these compounds are actual minerals or other silicates which crystallise out of the magma when it cools, we are also justified in making use of the properties of these minerals when we apply to the magma the known physico-chemical laws which govern solutions.

The number and nature of the minerals which can be in equilibrium with each other and the solution are to be determined by experiments upon their solubility interpreted by the phase-rule of Willard Gibbs, and especially by the laws which Roozeboom and other physical chemists have deduced for components which form double salts or isomorphous mixtures. Knowing the components we ought, therefore, to be able to determine their latent heat of fusion, their specific heat, the lowering of the freezing point of their mixtures, and from these data to calculate the true formulæ of the rock-forming minerals. It will readily be understood that in a mixture of quartz and orthoclase, the lowering of the freezing point below that of either of the constituents, as calculated by van 't Hoff's formula, from their melting points, latent heats, and molecular weights, will be very different according as the formula of quartz is taken to be SiO_2 or Si_3O_6.

Vogt boldly attacks the whole problem as one that can be solved on these lines; we have good reason to believe that the slags and rock-magmas are solutions; we know their constituents; we can therefore proceed to experiment with these constituents and to predict the behaviour of their mixture according to the principles of physical chemistry. The order of crystallisation is mainly determined by the relative composition of the magma and the eutectic, and the composition of the eutectic may be calculated from the intersection of the freezing-curves.

One interesting result is the conclusion that in the silicate magmas which have been the subject of experiment the minerals produced are all of very simple constitution; that, for example, olivine, diopside, akermanite, melilite, and anorthite have the simplest possible formulæ corresponding to their analyses and are not polymerised. Mineralogists will welcome this conclusion if it be true, for it has occasionally been the fashion on theoretical grounds to attribute a high degree of polymerisation to many minerals, and nothing is easier than to account for many difficulties if one may multiply the formula of a mineral by any number that is required. It should be added, however, that Doelter, calculating from his own experiments, is led to think that some of the minerals must have formulæ which are multiples of their empirical formulæ.

Vogt even goes a step further in his application of the principles of modern chemistry. The order of crystallisation appears to be by no means always that of the solubility, but indicates that a mineral is sometimes not so soluble as might be supposed. Now another principle in the modern physics of solutions is that by adding to a solution of one substance a new electrolyte containing an ion common to both the solubility of the first is diminished, and Vogt does not hesitate to apply this principle.

Thus spinel and felspar in mutual solution, when felspar is in large excess, should on cooling yield felspar first. But in many basic rocks spinel is the first to crystallise; this is, according to Vogt, due to the presence of ferromagnesian silicates containing the Mg-ion which is also present in spinel; if these be partially dissociated the solubility of the aluminate will be lowered.

An obvious criticism on this argument is that if the dissociation is so slight that it may be ignored for one purpose, it is hardly fair to invoke its powerful action for another, and it is possible that Vogt in his enthusiasm for a theory attempts to explain too much by its aid.

It is clear, however, that the labours of Vogt have been precisely in the direction indicated by Teall in the words that I have quoted, "experiment controlled by the modern theory of solution"; and if his opponents are tempted to think that he may have carried the principle too far with insufficient data, they cannot but admire the brilliancy, the persistency, and the ingenuity with which he has applied the newer theories of solution at every turn.

Heycock and Neville's Work on Alloys.

I must next refer briefly to another remarkable series of researches which have recently been published.

The laws which govern the solutions of metals in metals, that is to say alloys, appear to be the same as those which prevail in the case of other solutions; it is in alloys that the nature of eutectic mixtures has been most fully studied; and the phase-rule and Roozeboom's deductions from it have been applied with signal success to their investigation. A new impulse has been given to the subject by the work of Heycock and Neville which is summarised in their Bakerian lecture delivered last year upon the copper-tin series of alloys. They have studied the changes which occur during the cooling of an alloy by taking small ingots of the cooling metal and chilling them at certain temperatures; this arrests the gradual process of cooling and causes all that is liquid at the moment of chilling to become suddenly solid; it is then possible by polishing and etching the ingot to show the solid crystals set in the congealed ground-mass and to study their nature. They have been able to interpret their results by means of Roozeboom's remarkable work on the solidification of mixed crystals published in 1899. For our present purpose it is sufficient to consider these results as applied only to alloys. If a diagram be constructed with the temperatures for ordinates and constitution for abscissæ, Roozeboom has shown that two curves may be drawn. The first is the freezing-point curve, or *liquidus*, giving the temperatures at which an alloy of any composition begins to solidify: this is a broken curve and each section of it represents the temperature of equilibrium between the liquid and a different solid alloy; the breaks represent the temperatures and constitution of the liquid at which one solid ceases to be produced and another begins. The curve is, of course, far more complicated than the simple V of Meyerhoffer, since that represents the cooling of a mixture the constituents of which do not form compounds or isomorphous mixtures, whereas the alloys do both. In this respect the alloys resemble a silicate magma which is crystallising as a rock-mass: indeed it will be remembered that Mendeléeff insists upon the general similarity of silicon compounds to metallic alloys.

The second curve of Roozeboom is the melting-point curve, or *solidus*, representing the temperatures at which an alloy of given composition becomes completely solid. Points above the liquidus represent the condition of alloys which are completely liquid; points below the solidus that of alloys which are completely solid; points between the two that of cooling alloys which are only partially solid; and the curves themselves show which solid compounds can be in equilibrium with the liquid and with each other at any temperature.

The cooling-curves of Roberts-Austen and Stansfield had shown that considerable evolutions of heat may occur in cooling alloys far below the temperature of solidification, indicating that changes are going on in the solid as well as in the liquid condition. Heycock and Neville carry their investigations below the temperature of complete solidification and study these changes also.

In the case of the copper-tin series of alloys they find that, according to the temperature and constitution of the liquid, crystals belonging to no less than six different types may separate, namely:—

α, a solid solution of Cu with less than 9 per cent. of Sn.
β, a solid solution of Cu with less than 27 per cent. of Sn.
γ, of which the constitution is not known.
δ, which probably has the composition Cu_4Sn.
η, which probably has the composition Cu_3Sn.
H, which probably has the composition CuSn.

Both β and γ are unstable at ordinary temperatures. The compound δ crystallises out of β or γ while they are already in the solid state, when the temperature falls sufficiently.

A glance through the 101 photographs of chilled and etched ingots which accompany Heycock and Neville's paper on this series of alloys shows how impossible it would be from the final composition of the solid alloy to ascertain the various stages through which it has passed during cooling; as the authors remark, it is of the nature of a palimpsest. For example, the alloy, containing 14 atoms of tin to 86 of copper, consists at 800° of α crystals in a ground-mass which probably contains β; it solidifies at about 775°; at 675° there are only β crystals; at 600° there are α and β crystals, but here α has crystallised out of β after it became solid; at 530° there is a much larger proportion of α; at 470° there are α crystals immersed in a mixture of α and δ into which the residual β has broken up on cooling.

If the course of events is so complex in an alloy of only two metals, how much more difficult must it be to decipher in the case of a mass of complicated silicates which are even more prone to form isomorphous mixtures, such as we have in a solid rock, not to mention the additional presence of aluminates, oxides, and sulphides. And yet geologists are accustomed to speculate freely about the crystallisation of rock constituents from the magma without taking account of anything save the final stage.

I cannot help thinking that the experimental method of Heycock and Neville will have to be applied to the study of slags and fused silicates if we are to trace successfully the evolution of rock species. The value of their work to geologists is not only that the results are skilfully interpreted by the light of modern physical chemistry, but primarily that it is experimental work upon actual crystallising materials.

Supersaturated Solutions.

I do not myself see how we can do otherwise than apply to the study of rock-magmas all that can be learnt from physical chemists concerning the behaviour of solutions, for though we cannot attain in laboratory experiments the high temperatures and great pressures at which rocks may have crystallised, there is no reason to believe that these introduce more than a difference of degree. The principles of equilibrium between the various crystallising components probably remain the same, whatever may be the temperatures and pressures at which they have solidified.

It must at the same time be confessed that most of the experiments upon which the modern theory of solutions has been built up have been conducted upon dilute solutions, whereas the problems of crystalline growth are concerned, not with dilute nor even with saturated solutions, but only with solutions which are supersaturated. There is some force in the objection of Doelter that the results of such experiments may not be directly applicable to crystallising slags.

For example, as I have already mentioned, doubt has been expressed in the case of silicate magmas, whether the substances in solution are the minerals about to crystallise or only their constituents; whether viscosity and supersaturation may not invert the theoretical order of their appearance; whether we are to take into account possible dissociation of the molecules or not; whether the presence of a common ion in these minerals is a factor which determines their mutual solubility. In fact, very little is known about the actual condition of the materials in a strong solution, although I do not know that there is any evidence available which forbids us to regard a solution about to crystallise as a mixture of liquids one of which is about to pass into the solid state.

But if little is known about the nature of strong and supersaturated solutions, a good deal may be learnt about their behaviour. Having complained that we need experiments in this field, I may perhaps be pardoned if I allude to some unpublished experiments of my own which relate to the general behaviour of crystallising liquids, and appear to me to explain two difficult problems in petrography. To such experiments the objection of Doelter does not apply.

The Metastable and Labile Conditions.

When a solution of any salt such as alum or sodium nitrate is allowed to crystallise at a uniform temperature the crystals will only grow so long as the solution is supersaturated; a crystal growing in the supersaturated solution will continue to do so until a condition of equi-

librium is attained. If the solution be kept at rest and maintained at a constant temperature, the crystal will continue to concentrate the liquid around itself and to withdraw solid material, until by diffusion of the impoverished liquid the whole mass is ultimately reduced to saturation, equilibrium is established, and the crystal ceases to grow; but most saturated solutions are so viscous that a very long time is required before this point is reached. Prolonged and vigorous stirring is required if the supersaturation is to be completely relieved within, say, a day; without stirring weeks may be required.

Further, it may be possible, as is well known, to keep a supersaturated solution in a sealed tube for years without change; and it is also possible to start crystallisation in such a liquid by dropping into it a crystal of the dissolved substance, or of one isomorphous with it, or sometimes by shaking it.

But it is, perhaps, not generally known that supersaturated solutions are of two sorts.

In 1897 Ostwald published some experiments upon supercooled liquids and supersaturated solutions, which were carried out with the object of showing how extraordinarily minute are the quantities of solid material capable of starting crystallisation in such liquids, but at the same time that they have a limit of size. He directed attention to the radical difference which probably exists between the state of a saturated solution which cannot crystallise spontaneously and that of the more strongly supersaturated solution which can do so.

The former is one in which crystallisation can either take place spontaneously or can be induced by stirring or shaking, or a variety of causes: this Ostwald calls the *labile* state. The latter is one in which crystallisation can only take place if a solid crystal of the dissolved substance, or a fragment of one, is brought into contact with the liquid: this he calls the *metastable* state. It is highly probable that no amount of stirring or shaking, or introduction of foreign substances, can make the metastable liquid crystallise.

Until recently no attempt to ascertain the exact limit between the metastable and labile states, or even to establish the existence of such a limit, had been successful, and practically no attention has been paid to the difference between them. Tamman, who measures the velocity of crystallisation by counting the number of the centres of growth or nuclei which appear in a supersaturated solution, does not recognise any distinction between the two states.

During the present year a number of experiments carried on by Miss F. Isaac and myself upon the strength of solutions from which crystals are growing have shown that it is easy to determine the changing concentration of a cooling solution by an optical method, to show that it passes into the labile state, and to ascertain the temperature at which the transition occurs. We have found, for example, that a solution containing 48 per cent. of $NaNO_3$ is saturated at 26°, is metastable between 26° and 16°, and crystallises spontaneously below that temperature; one containing 52 per cent. of $NaNO_3$ is saturated at 44°, and becomes labile at 35°.

In the metastable state inoculation by a solid germ of the dissolved substance, or of one isomorphous with it, is *necessary* in order to cause the liquid to crystallise; in the labile condition solid germs may be spontaneously generated from the liquid. Take, for example, a test tube filled with a solution of sodium-nitrate containing 48 parts of the salt in 100 parts of solution, which is metastable at ordinary temperatures; if crystals make their appearance in this solution it will only be because the dust of the room contains minute particles of sodium-nitrate which fall into the tube, or because crystals are deposited where drops have evaporated near the surface, and accordingly the first crystals appear at the surface of the liquid, and grow there until they are large enough to fall to the bottom. I find that such a solution, if enclosed in a sealed tube so as to prevent access of germs and evaporation, cannot be made to crystallise above the temperature of 16°, although it is supersaturated at all temperatures below 26°.

Again, let a hot solution of the same strength containing 48 per cent. of the salt be allowed to cool down while being stirred. If dust containing $NaNO_3$ can be excluded, the liquid will not crystallise until the temperature falls to 16°, when the solution passes from the metastable to the labile condition. A cloud of nuclei will then form throughout the liquid, and each will proceed to grow as a separate crystal; the immediate effect is to reduce the liquid to the metastable state so that no more crystals are produced, but each of these continues to grow from the liquid with which it is in contact.

If dust be not excluded, crystals may make their appearance upon the surface of the liquid and will soon sink; but even though they be stirred about actively in the solution the liquid as a whole remains in the metastable state until a temperature somewhat below 16° is reached, when the labile region is entered and a cloud of new crystals makes its appearance.

It follows, therefore, that in a cooling supersaturated solution, from which germs have not been excluded, there are normally two periods of growth: one in which a comparatively small number of isolated crystals are growing regularly, and a subsequent period in which a shower of small crystals is produced. Only if the rate of cooling be sufficiently slow, or the stirring be sufficiently violent, to keep the liquid in the metastable condition will there be no second period, no sudden precipitation of nuclei.

These events take place in all the aqueous solutions which I have examined, and I am surprised that they have not been discovered before. They afford a possible explanation of two common features of igneous rocks, and of slags—namely, the growth of comparatively large and isolated porphyritic crystals, or phenocrysts, and the appearance of the same mineral at two or more different periods. The origin and the arrested growth of phenocrysts have generally been attributed to sudden change of temperature, of pressure, or of hydration, and no other plausible explanation has been given, although, as has been sometimes pointed out, they may occur in batholites where there is no independent evidence of such changes. Pirsson has recognised the utter impossibility of the ordinary theory and has recently suggested that each mineral has its crystallisation interval during which it continues to grow, and that this is terminated by the increasing viscosity of the magma, which checks the supply of further material to the growing phenocrysts and establishes new centres of crystallisation. A similar explanation was adopted by Crosby for the quartz-porphyry of the Blue Hills. He expresses it by saying that owing to the increased viscosity the rate of cooling overtaxes the molecular flow, which cannot keep pace with the crystallisation. It is so difficult to find any satisfactory theory for the growth of phenocrysts that they have even been attributed to the effect of earthquake shocks.

Now in a silicate magma, in all probability, the temperature is sufficiently high to be that of the metastable condition, the rate of cooling sufficiently slow to keep the liquid in that condition for a considerable time, and the viscosity sufficiently great to prevent the growing crystals from sinking at once; we have, therefore, all the conditions favourable for the growth of *porphyritic* crystals; these must have generally originated throughout the liquid as spontaneous nuclei if the magma entered the labile state, or may have been started by inoculation or cooling at the margin if the magma as a whole remained in the metastable state. In the latter case suppose that further somewhat sudden cooling brings the magma to the labile condition, then there will be a sudden and spontaneous second growth of nuclei which will not be able to attain the dimensions of the porphyritic crystals; we have here all the conditions necessary for a *second generation* of one of the constituents of the rock.

It is not necessary, therefore, to suppose that changes of pressure played any very great part in these matters. I believe it will be found that considerations of temperature and solubility are far more important. Similarly in the case of the salt deposits van 't Hoff came to the conclusion that practically the only effect of changes of pressure is to displace the temperature of formation of the various compounds and not to alter their order or their nature; he estimates that this displacement is comparable with that of the melting points under the same agency, and in the case of the calcium-magnesium chlorides only amounts to a few thousandths of a degree for one atmosphere of pressure.

Perhaps when we can ascertain the temperature at which silicate magmas pass from the metastable to the labile condition we may use this knowledge to determine the exact temperature at which certain of their minerals crystallised.

Ordinary petrographical descriptions supply numerous examples of the difference between the metastable and labile conditions to anyone who will read them in the light of the suggestion which I have made; others are to be found in such experiments as those of Vogt or Doelter.

My own hope is that when more experiments have been made upon mixed *supersaturated* solutions it will be found that most, if not all, of the features of rock development are paralleled by the ordinary processes of crystallisation, but that motion, supersaturation, and supercooling are most important factors.

The very similarity between the differentiation of the alumo-alkaline and ferro-magnesian minerals on a small scale in the rock, and that of the alumo-alkaline (or salic) and ferro-magnesian (or femic) rocks themselves on a large scale, points to some similarity of origin.

In order to avoid burdening this Address with detail I have merely chosen the researches of van 't Hoff, Vogt, Doelter, and Heycock and Neville as illustrations of experimental work conducted on the lines of modern physical chemistry, and have omitted much that might have been mentioned; the valuable researches of Pelouze, Lagorio, Morozewicz, and Loevinson-Lessing, and the melting-point determinations of Joly I have not quoted, because they belong for the most part to an earlier period than that which I am considering, and have been discussed by Teall and other writers.

Many very interesting speculations I have passed over entirely, because my object has been to focus attention upon experimental evidence. I cannot help thinking that these speculations are often based upon chemical actions and equilibria that may be impossible; but we cannot criticise them for lack of evidence, and I return to my original statement that geology is only beginning to enter the experimental stage.

An earnest beginning is, however, being made. The researches on mineral and rock synthesis which I have already quoted are laying a solid foundation; and I see no reason why something of the sort which has been done by van 't Hoff and his collaborators for the aqueous deposits of Stassfurt should not ultimately be worked out for an igneous complex, though it may involve tenfold the labour and tenfold the time. We have already to welcome the establishment by the United States Geological Survey of a laboratory for the express purpose of applying to minerals and rocks the exact methods of modern physics and physical chemistry. The very suggestive research of Day and Allen upon the thermal properties of the felspars is a promise of the sort of work that may be expected from such laboratories.

I fear it will be only too evident to those who have given me their patience during this Address that I approach the problems considered in it from the point of view, not of the geologist or the chemist, but of the crystallographer, to whom the birth and growth of crystals are a study in themselves. Whether we watch with the microscope a tiny crystal growing from a drop of solution, or contemplate with the imagination the stages by which the fiery lavas of past geological periods sank to rest and crystallised, we view the same process; it is the transformation of liquid into crystal. Not necessarily into a solid, for recent research shows that there is no dividing line between liquid and solid; a plastic solid body may flow; a solid glass is only a supercooled liquid; witness, for example, the experiments of Adams on rocks, and of Tamman on supercooled liquids. The real primary distinction is between crystalline and non-crystalline material, and there is even good reason to believe that some crystals are liquid without ceasing to be crystals.

The properties of most rocks, of metals, alloys, ice, and many other substances are due to the fact that they consist of crystals, and the importance of the study of the latter is now, I trust, being brought home alike to chemists, physicists, geologists, and engineers in connection with problems relating to the strength, the movements, the origin and changes of what are usually called solids.

And so I close, as befits a student and teacher of crystallography, with the hope that renewed attention may be paid to this subject, and that it may attract the interest of many a keen intellect in South Africa. The higher scientific studies are now establishing themselves as an integral part of the educational and intellectual life of the country: this is in no small measure due to the South African Association; and we may hope that the visit of the British Association will be of some help to her younger sister in the task of diffusing a taste and an interest for the pure truths of science and the studies that they both hold dear.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY G. A. BOULENGER, F.R.S., V.P.Z.S., PRESIDENT OF THE SECTION.[1]

The Distribution of African Fresh-water Fishes.

I THINK I may ascribe the honour of having been chosen to preside over this Section to the fact that I have specially applied myself to the study of a large class of the animals of the part of the world in which we are for the first time assembled. The subject of the Address which it is the custom to deliver on such an occasion was therefore not difficult to choose—a general survey of the African fresh-water fishes from the point of view of their distribution.

It has repeatedly been pointed out that no division of the world can answer for all groups of animals, differences due to the period at which they appeared and to their ability or inability to spread over obstacles, whether of land or water, precluding any attempt to make their present distribution fit into the frames of the general zoogeographer. The great divisions of the earth, as outlined by our eminent Vice-President, Dr. Sclater, nearly half a century ago, and based mainly on a study of passerine birds, have therefore varied considerably according to the standpoint of the many workers who have followed in his footsteps. Fresh-water bony fishes particularly lend themselves to a uniform treatment, their principal groups having sprung up, so far as palæontological data teach us, about the same period in the history of the earth, and branched off in many directions within a geologically speaking brief lapse of time, most of them, besides, being regulated in their distribution by the water-systems. How greatly their distribution differs from that of terrestrial animals has long ago been emphasised. Thus, latitudinal range, so striking in many African reptiles, does not exist in fishes: the key to their mode of dispersal is, with few exceptions, to be found in the hydrography of the continent; and, as first shown by Dr. Sauvage, latitude and climate, excepting of course very great altitudes, are inconsiderable factors, the fish-fauna of a country deriving its character from the head waters of the river-system which flows through it. In this way, for instance, the Lower Nile is inhabited by fishes bearing a close resemblance to, or even specifically identical with, those of Tropical Africa, and strikingly contrasting in character with the land-fauna on its banks. Such being the case, it seems at first as if the geographical divisions of the fish-fauna were a matter of extreme simplicity, and that a knowledge of the river-systems ought to suffice for tracing areas which shall express the state of things. But we must bear in mind the movements which have taken place on the surface of the earth, and owing to which the conditions we find at present may not have existed within comparatively recent times; and this is where the systematic study of the aquatic animals affords scope for conclusions having a direct bearing on the physical geography of the near past. To mention two examples, the fishes of the Nile show so many specific types in common with those of the Senegal-Niger, now more or less completely separated by the Chad basin, that we felt justified in postulating a recent communication between these water-systems, which has been fully confirmed by the study of the Lake Chad fishes; whilst, on the other hand, the greater difference between the fishes of the Nile and those of the Congo basin, the waters of which interlock at pre-

[1] Slightly abridged.

sent in such a way that it is believed possible, at certain seasons, for a man in a boat to pass from the one into the other, points to the existence, until very recently, of a more effective separation. Such problems are of the greatest interest, and a more exact knowledge of the fishes will help towards their solution.

There is another aspect of the question of geographical distribution which has assumed special importance of late, especially in the writings of Prof. Osborn, Mr. Lydekker, and Dr. Scharff, and of which Dr. A. E. Ortmann's paper on the distribution of Decapod Crustaceans, published three years ago, may be taken as an example. One of the conclusions formulated therein is that "any division of the earth's surface into zoo-geographical regions which starts exclusively from the present distribution of animals without considering its origin must be unsatisfactory." But in certain groups of animals, possibly in most, the question of their origin is not easily settled; in the case of the African fresh-water fishes, for instance, we sadly lack all direct palæontological data, such as have sprung up lately in marvellous profusion in the case of the mammals, and notwithstanding the great progress in our knowledge of the changes that have taken place in the configuration of the world in Secondary and Tertiary times, which has been conveyed to a wide circle of readers chiefly through the luminous works of Neumayr, Suess, and de Lapparent, there is still much that is open to discussion. It must be admitted—and it is well to draw special attention to this point—that Dr. Ortmann's maps of the land-areas in past periods, which render his suggestive paper so attractive, cannot be accepted as the expression of well-established geological facts, and are, in some respects, gravely misleading. If I have attempted to deal with this subject on the lines laid down by Dr. Ortmann, whilst realising the want of many necessary data, palæontological and geological, on which to base conclusions, it is with a due sense of humility, being fully aware that the suggestions now offered must be regarded as mere speculations.

The time has come for a stock-taking of our immensely increased material, the previous accounts of the distribution of African fishes given by Dambeck in 1879, by Günther and by Sauvage in 1880, and by Palacky in 1895, no longer answering, even approximately, to our present knowledge, as may be seen by comparing the lists given by these authors with the one I have quite recently published in the *Annals and Magazine of Natural History* as a basis for the sketch here attempted.

How little we knew of the fresh-water fishes of Africa when the subject was dealt with by the above-named authors is exemplified by the enormous number of genera and species which have been discovered within the last few years, thanks chiefly to the enlightened activity of the Governments of Egypt and the Congo Free State, and to the initiative of Prof. Ray Lankester in organising explorations of the great lakes of Central Africa. The waters of the French Congo and Cameroon, the Niger, Abyssinia, and the interior of East Africa, have also yielded a large number of novelties; even the Nile, comparatively so well known, has been productive of many and remarkable additions to our knowledge. The importance of a better acquaintance with the fishes of the Lower Nile, a district believed to have been particularly well explored, can be measured by comparing the present data with those to which Prof. Gregory, on the faith of Dr. Günther's list, appealed to justify his theory of a direct connection in the past of the Upper Nile with the Jordan through a river flowing along what is now the Red Sea. To this question we shall revert presently.

Whilst the exploration of rivers and lakes has resulted in such a rich harvest, it remains a matter for serious regret that we should still be without any information as to the precursors of the African fishes. In spite of diligent search over a considerable portion of the great continent, no remains of any post-Triassic fishes have yet been discovered in Tropical and South Africa, and our acquaintance with Tertiary Teleosts generally is still almost as scanty and fragmentary as it was twenty years ago, although much has been done by Dr. Smith Woodward in elucidating the affinities of such remains as have been exhumed. In the circumstances we have to fall back on our imagination to explain the origin of the most important groups characteristic of the present African fish-fauna, and much hazardous speculation has been indulged in. Thus, without any sort of evidence, the Cichlid Perches of Africa have been supposed to emanate from ancestors inhabiting hypothetical Jurassic or Cretaceous seas extending over Central Africa, whilst connecting land areas have been too freely postulated to account for the resemblance between the fishes of Africa and Tropical America, and antarctic continents devised to explain the presence of Galaxias in South Africa. To these suggestions I shall refer further on when dealing with the distribution of the families to which they were intended to apply. Although it is highly desirable that zoologists should base their theories of geographical distribution upon geological data, I think we must regret the growing tendency to appeal to former extensions of land or sea without sufficient evidence, or even contrary to evidence, in order to explain away the riddles that offer themselves.

Twenty-five years ago a list of the African fresh-water fishes would have included the names of about 350 species (Günther gave the number as 255 only), some fifty of which have since lapsed into the synonymy, whilst at the present day we are acquainted with 976 species, referable to 185 genera and forty-three families. Of the latter five were then unknown, or unknown to have representatives in this part of the world. The forty-three families are here enumerated, with an indication of the number of genera and species according to the most recent census:—

CHONDROPTERYGII.

PLAGIOSTOMI.

1. Carchariidæ, 1, 1.
2. Pristidæ, 1, 1.

CROSSOPTERYGII.

CLADISTIA.

3. Polypteridæ, 2, 11.

DIPNEUSTI.

4. Lepidosirenidæ, 1, 3.

TELEOSTEI.

MALACOPTERYGII.

5. Elopidæ, 2, 3.
6. Mormyridæ, 11, 108.
7. Notopteridæ, 2, 2.
8. Osteoglossidæ, 1, 1.
9. Pantodontidæ, 1, 1.
10. Phractolæmidæ, 1, 1.
11. Clupeidæ, 6, 7.
12. Salmonidæ, 1, 1.
13. Cromeriidæ, 1, 1.

OSTARIOPHYSI.

14. Characinidæ, 20, 93.
15. Cyprinidæ, 12, 202.
16. Siluridæ, 37, 187.

APODES.

17. Anguillidæ, 1, 6.

HAPLOMI.

18. Galaxiidæ, 1, 2.
19. Kneriidæ, 1, 2.
20. Cyprinodontidæ, 5, 39.

CATOSTEOMI.

21. Gastrosteidæ, 1, 1.
22. Syngnathidæ, 2, 3.

PERCESOCES.

23. Scombresocidæ, 1, 1.
24. Atherinidæ, 2, 3.
25. Mugilidæ, 2, 13.
26. Polynemidæ, 3, 3.
27. Sphyrænidæ, 1, 1.
28. Ophiocephalidæ, 1, 3.
29. Anabantidæ, 1, 14.

ACANTHOPTERYGII.

30. Centrarchidæ, 1, 3.
31. Nandidæ, 1, 1.
32. Serranidæ, 6, 8.
33. Sciænidæ, 1, 1.
34. Pristipomatidæ, 2, 2.
35. Sparidæ, 1, 1.
36. Scorpididæ, 1, 3.
37. Osphromenidæ, 1, 1.
38. Cichlidæ, 30, 179.
39. Pleuronectidæ, 2, 2.
40. Gobiidæ, 2, 31.
41. Blenniidæ, 3, 3.

OPISTHOMI.

42. Mastacembelidæ, 1, 23.

PLECTOGNATHI.

43. Tetrodontidæ, 1, 4.

In discussing the distribution of the fresh-water fishes it is necessary to divide them into four principal categories:—

(1) Those living part of the year in the sea. This category is again subdivided into anadromous forms, breeding in fresh water (ex. some Clupea), and catadromous forms, breeding in salt water (ex. Anguilla).

(2) Those living normally in the sea, but of which certain colonies have become land-locked, or have separated themselves from the marine stock still represented on the neighbouring coast (ex. some Gobiidæ and Blenniidæ).

(3) Those which, although entirely confined to fresh waters, have as nearest allies species living in the sea, and which there is reason to regard as more or less recently derived from marine forms (ex. Galaxiidæ, Tetrodontidæ).

(4) Those belonging to families entirely (ex. Mormyridæ, Characinidæ) or chiefly (ex. Siluridæ, Cyprinodontidæ) restricted to fresh waters.

The forms of the first and second categories may be entirely neglected in dealing with the distribution of fresh-water fishes. Their range is regulated by the sea, and they must be dealt with in conjunction with littoral forms. Eighty-six species in the list of African fresh-water fishes belong to these categories.

The third category is of secondary interest in the history of the fresh-water fauna; but, as in the case of Galaxias, forms referred to it may give rise to discussion.

It is with the members of the fourth category that we shall mainly deal in the portion of this Address which is devoted to the origin and mode of dispersal of the African fishes.

THE POLYPTERIDÆ.—This is incontestably the most remarkable family of African fishes. Entirely restricted to Tropical Africa and the Nile, without any known near allies, living or extinct, its history is one of the greatest riddles in ichthyology. From the evolutionary point of view, no group is of greater interest, owing to its probable relation to the Chondropterygians or Elasmobranchs, to the Osteolepid Crossopterygians, out of which the Lung-fishes seem to have been evolved, and to the earliest pentadactyle vertebrates, the Stegocephalous Batrachians. Although generally brigaded by modern systematists with the Osteolepida in the order Crossopterygii, it is still doubtful whether it should not rank as a distinct order, Cladistia of Cope, the characters which differentiate it from these early Teleostomes being perhaps of greater importance than those which separate these from the Dipneusti. Until we have some proof to the contrary, we are justified in regarding the Polypteridæ as having arisen in Africa from fresh-water ancestors, themselves derived from early Mesozoic types which are entirely hypothetical.

THE LEPIDOSIRENIDÆ.—Protopterus in Africa and Lepidosiren in South America are specialised modifications of the Ceratodontidæ, still represented by one species in Australia, which have left remains in Triassic, Rhætic, Jurassic, and Cretaceous rocks of Europe, North America, Patagonia, North and South Africa, India, and Australia. The distribution of the Ceratodontidæ has therefore been, at different periods at least, a world-wide one, and we should feel justified in assuming the living representatives of the Lepidosirenidæ to have been evolved out of this family independently in Africa and in South America. On the other hand, in view of the old age of the group, there is no reason why the Lepidosirenidæ should not have passed from one of the present continents into the other when they were connected by land. As Protopterus is a less specialised type than Lepidosiren, the probabilities would then be that the former originated in Africa. Mr. Lydekker, in his "Geographical History of Mammals," states his opinion that Lepidosiren reached its present habitat by way of Africa. The mode of life of these fishes renders them less dependent on hydrographical systems, and the distribution of the species, which cannot yet be traced in a satisfactory manner, is evidently very different from that of other groups.

THE MORMYRIDÆ.—This extraordinary group, of which so many new and remarkable types have been discovered within the last few years, especially in the Congo, is peculiar to the fresh waters of Tropical Africa and the Nile. Its morphology shows it to be highly specialised from some very lowly Teleostean ancestor. This I believed to be found in the Albulidæ, a family already represented in Cretaceous seas, and of which one species still occurs on the West Coast of Africa. But Dr. Ridewood, who has recently made a much more careful study of the cranial characters of the two families, is unable to support the suggestion of a direct descent from the Albulidæ. It nevertheless remains probable that the Mormyridæ were derived from forms more closely allied to the known Albulidæ than to any other family with which we are acquainted, and which no doubt lived in Cretaceous seas; and we may therefore assume that the Mormyridæ originated in Africa, and were evolved out of Cretaceous marine ancestors.

THE NOTOPTERIDÆ.—This is another eccentric family, having many points in common with the Mormyridæ and with the North American Hyodontidæ. It is represented by five species, three of which live in the Indo-Malay region and two in Tropical Africa. Its derivation is still a mystery. The fact that its most specialised form (Xenomystus) is African, and that a species differing but little from the living Notopterus occurs in fresh-water deposits in Sumatra, which are regarded by some geologists as of Middle Eocene age—although, as stated further on *à propos* of the Cyprinidæ, there is reason for regarding them as Miocene, or even later—justifies us in believing, until further palæontological evidence be available, that the African forms are immigrants from the East.

THE OSTEOGLOSSIDÆ.—An archaic type of Teleosteans, now represented by two genera in South America, by one in Australia and the Malay Archipelago, and by a fourth in Tropical Africa and the Nile. Excellently preserved fossils from the Middle Eocene of Wyoming (Dapedoglossus) are most nearly allied to, but more generalised than, the Australian-Malay genus; whilst the less satisfactorily known British Lower Eocene Brychætus appears nearer to the South American Arapaima. The African genus Heterotis is the most specialised form. The Osteoglossidæ are evidently an ancient group, now in process of extinction, which once had a very wide distribution. The fact of the only known fossil representatives being from North America and Europe does not seem sufficient evidence of the northern origin of the family, as suggested by Mr. Lydekker.

PANTODONTIDÆ, PHRACTOLÆMIDÆ, CROMERIIDÆ.—Three monotypic families peculiar to Africa. The first bears a near relationship to the Osteoglossidæ, and was probably derived from them; but the two others, discovered within the last few years, are so aberrant and isolated among the Malacopterygians that we are absolutely in the dark as to their possible origin.

THE CHARACINIDÆ.—This is one of the larger groups of African fishes—with ninety-three species, referred to twenty genera, mostly from the Nile and Tropical Africa, as far east as the great lakes, but only very sparsely represented in East and South Africa.

One of the most striking features of the South American fresh-water fish-fauna is the extraordinary number and variety of forms of the Characinidæ, unquestionably one of the most lowly and generalised groups of exclusively fresh-water Teleosts. There occur in that part of the world as many as 500 species (about two-fifths of the whole fresh-water fish-fauna), divided among some sixty genera. The carnivorous forms predominate, but the herbivorous or semi-herbivorous are also very numerous. The latter would evidently compete with the Cyprinids, their near but more specialised relatives, which are so numerously represented in North America; and it is a remarkable fact that not a single Cyprinid is known to extend further south than Guatemala.

Although palæontology has taught us nothing respecting the Characinids, we have reason to assume, from the morphological point of view, that they were the precursors of the Cyprinids, which, we know, were already abundantly represented in North America and Europe in Lower Tertiary times, when the Isthmus of Panama was under the sea. When, in the Miocene, North and South America became re-united, the waters of the latter part of the world must have been already so fully stocked with Characinids as to prevent the southern spread of the Cyprinids. This is the only explanation that can be offered of the total absence of Cyprinids in South America, considerations of climate being of no avail in view of their distribution all over Africa. If, therefore, the Characinids existed in profusion in South America before the Miocene period, we are justified in claiming for them a high antiquity, and by putting it at the Upper Cretaceous we need not fear going too far back.

THE CYPRINIDÆ.—These fishes, as mentioned above, are very closely related to the preceding, and there is every reason to believe the former to be derived from the latter. Their least specialised genera (Catostominæ) are now found in North and Central America (about sixty species), whilst three species, referable to the same genera, inhabit Eastern Siberia and China. These Catostominæ are known to have had representatives in the Eocene of North America, whilst the more specialised Cyprininæ, which

constitute the great bulk of the family both in the new world and in the old, have left remains in the Oligocene and later beds in North America and Europe. It is, therefore, highly probable that the Cyprinids originated as a northern offshoot of the South and Central American Characinids, and thence spread to Eastern Asia, at least as early as the Upper Eocene. By the time (Miocene) they had reached India, where they now form the great majority of the fresh-water fishes, Africa had been connected with it by a wide belt of land, and no obstacle prevented their western extension. This comparatively recent migration accounts for the practical identity of the genera and the often very close affinity of the species of the Cyprinids of India and Africa. At the same period the land-area connecting India and Africa with Madagascar had disappeared, and the Cyprinids never reached that great island, where no doubt they would have thriven, if we judge by the results of the introduction by man of the gold fish, said to be in process of strongly reducing the numbers of the native Malagasy fresh-water fishes with which it is in a position to compete. Competition is always an important factor in the distribution of a group of animals, and the confinement of the Characinids to the waters of the western and central parts of Africa at the time of the immigration of the Cyprinids from the east must be the explanation of the comparative abundance of the latter and the scarcity of the former in those parts of the continent east of the Rift Valley which are not drained by rivers flowing from the central parts. The Cyprinids must have spread more rapidly than the Characinids, and being also less partial to heat they have thriven in the waters of South Africa, where at present only two species of Characinids—both carnivorous forms—are known to extend south of the Zambesi system. Of the 202 species recorded from Africa thirteen are found in North-West Africa, sixty-three in East Africa (exclusive of the Zambesi), and twenty-one in South Africa.

THE SILURIDÆ.—This large family is almost cosmopolitan in tropical and warm regions; and although the great bulk of the species are restricted to fresh waters, a certain number (chiefly of the sub-family Ariinæ) occur on the coasts and in the estuaries. Morphologically these fishes are so closely allied to the Characinidæ and Cyprinidæ that we must assume them to have been evolved from a common ancestral stock, probably in Cretaceous times; but connecting forms such as we should expect to find in deposits of that age are still unknown. The Silurids appear in the Lower Eocene estuarine beds of England and France, as forms closely related to the living Ariinæ and Bagrinæ, and further allied forms follow in the Middle Eocene of various parts of Europe and North America. In the Upper Eocene of Lower Egypt estuarine deposits contain well-preserved remains of forms which appear to be only specifically separable from the Bagrus still living in the Nile. The general distribution of these fishes was, therefore, in early Tertiary times very much the same as it is at present, and palæontology offers us no clue as to where they originated.

The exclusively fresh-water Silurids now found in Africa are all generically distinct from the South American forms, whilst the West African species that enter the sea belong to the same genus (Arius). The two exclusively fresh-water Silurids found in Madagascar show closer affinity with the African than with the Indian forms, and may have immigrated from Africa in the early Tertiary times through the bridge which then existed, unless they have been derived from marine types, which is quite possible.

THE GALAXIIDÆ.—Two small fishes originally described by F. de Castelnau as Loaches, and now referred to Galaxias, occur on the flats near Cape Town and in the Lorenz River, some twelve miles from its mouth in False Bay. They are of special interest as belonging to a family and genus long believed to be exclusively confined to fresh waters and characteristic of the extreme south of America, New Zealand, and Southern Australia. After Dr. Steindachner had first recognised the true affinities of the Cape species, Prof. Max Weber was inclined to regard this interesting discovery as affording a new argument in favour of the past antarctic continent on which so much has been written. But Dr. Wallace was nearer the truth when he suggested that a land connection within the period of existence of one species of fish, viz. *Galaxias attenuatus*, known from Chili, Patagonia, Tierra del Fuego, the Falkland Islands, New Zealand, and Southern Australia, would have led to much more numerous and important cases of similarity of natural productions than we actually find, and that we must rather look to the transport of the ova across the southern sea to explain this very remarkable distribution. A better acquaintance with the Galaxias has confirmed Dr. Wallace's supposition, as it is now an established fact that some species live in the sea.

As the early Tertiary "Antarctica," as designed by Prof. H. F. Osborn, does not involve South Africa, the presence of species of Galaxias at the Cape cannot, even on that hypothesis of continental extension, be explained except on the assumption of their marine origin.

THE KNERIIDÆ.—A monotypic family with two species, one from Angola, the other from East Africa. These little fishes are related to the Pikes, Esocidæ; and there is no reason that I can see against their being possibly derived from them, in which case they would be of northern origin, the Esocidæ, now confined to the northern hemisphere, being known from fresh-water deposits in Europe as far back as the Oligocene.

THE CYPRINODONTIDÆ.—The members of this large family are mostly Central and South American. They are comparatively few in Africa, but have representatives in every part, and also in Madagascar and the other islands of the Indian Ocean. Although principally restricted to fresh waters, not a few species are known to live in brackish water, whilst examples are known of their occurring far out at sea.

THE OPHIOCEPHALIDÆ AND ANABANTIDÆ.—Unknown fossil, and now restricted to Africa and South-Eastern Asia, we have no means of telling in what part of the world these two closely allied families originated. The Anabantidæ are more numerous in species, and these are of a more generalised type, in Africa than in Asia.

THE NANDIDÆ.—The recent discovery of Polycentropsis in the Lower Niger has added a genus to a small family previously known to be represented by three genera in South-Eastern Asia and by two in the northern parts of South America. The latter are more nearly related to the African genus than the former. Too little is known of the habits of these fishes to decide whether the hypothesis of a migration across the Atlantic, in the days when a shallow area with a string of islands connected the old world and the new, answers for their distribution. Their systematic position—specialised Perciformes—is against the assumption of their having existed in Cretaceous or early Eocene times. No fossil forms are known.

THE OSPHROMENIDÆ.—The only African representative, the genus Micracanthus, with a single species in the Ogowé, is hardly separable from the genus Betta, which, with six other genera, is characteristic of the Indo-Malay region and China. Palæontology gives no information on the earlier distribution of these highly specialised fishes. That a type so well organised for adapting itself to all sorts of waters, and so ready to acclimatise itself in any part of the tropical or subtropical countries where it has been transported by man, should have so restricted a range seems remarkable. Were it not for the existence of this African form, far away from the other members of the family, one might have felt inclined to look upon the Osphromenidæ as a very recent group, which has not had time to spread far from its original centre in South-Western Asia.

THE CICHLIDÆ.—As regards the number of species (179) this family ranks next to the Cyprinidæ (202) and the Siluridæ (187) in the African fresh-water fish-fauna, and, like these, it has representatives nearly all over the great continent. Although Cichlids may thrive in inland waters of considerable salinity, they are not known to have ever been found in the sea, even near the mouths of rivers. The facility with which they establish themselves in isolated waters, often untenanted by other fishes, such as wells in the Sahara, salt-water pools in the interior of East Africa, &c., has long been known, but by what agency this has been effected remains unexplained. Quite recently Dr. Lönnberg has reported on the exploration of a small

isolated lake of volcanic origin on the Cameroon mountain, a lake 200 feet above sea-level, without any outlet, and situated about twelve miles from the nearest river and twice as far from the sea-shore. This lake was found to have a fish-fauna consisting exclusively of Cichlids, belonging to three genera and five species, two of which have been described as new.

The great bulk of the family inhabits Africa, including Madagascar, and America, from Texas to Montevideo; the number of generic types is greater, although the species are only slightly in excess, in the former than in the latter part of the world. Seven species inhabit Syria, three of these being also found in the Nile, and three are known from India and Ceylon. The American and Indian genera are all distinct from the African. A great number of species (fifty-five), all but one endemic, inhabit Lake Tanganyika, of which they form a little more than two-thirds of the fish-fauna; and many of these species belong to distinct genera, showing specialisation to a remarkable degree. Out of thirty recognised genera of African Cichlids, as many as fifteen are believed to be peculiar to Tanganyika. Lake Nyassa, with the Upper Shiré, possesses also some remarkable endemic genera; but they are only four in number, and the number of species recorded up to the present does not exceed twenty-two. The rest of the species are mostly from West Africa and the Congo basin; but a few, referable to the two most widely spread genera, are found in East and South Africa. Madagascar has only four species, two belonging to an endemic genus, whilst each of the two others is referred to a widely distributed African and Syrian genus.

No fossils are known that agree closely with any of the recent genera, but a type of Perciforms, described by Cope as Priscacara, from Middle Eocene fresh-water beds in North America, presents all the characters which we should expect to find in the direct ancestors of the modern Cichlids, differing from the living forms in the presence of vomerine teeth, a serrated præ-operculum, and apparently eight branchiostegal rays. It has twenty-four vertebræ, a number lower than is found in most of the recent genera; and this indication is of importance for reasons that must be explained somewhat fully.

The lower Teleosteans (Malacopterygii and Ostariophysi, often united under the term "Physostomi") mostly have a high number of vertebræ; but when we pass on to the higher Acanthopterygii, we find very frequently, among most diverse families, the number reduced to twenty-four. That this number should occur with such frequency has struck many ichthyologists since Dr. Günther first directed attention to it, more than forty years ago, pointing out at the same time that in the Labridæ this number is almost constant in the tropical genera, whilst those genera which are chiefly confined to the temperate seas of the northern and southern hemispheres have an increased number. It has since been shown by Dr. Gill and by Prof. Jordan that this generalisation holds true of several other families of Acanthopterygians, and the latter authority, when discussing the subject at some length, came to the opinion that the state of things could be explained, from an evolutionary point of view, on the assumption that competition among various marine fishes being greater within the tropics has resulted in greater specialisation, by which the originally high number of vertebræ has been reduced. It is difficult, however, on this assumption to account for the fact that in so many cases the reduction should have resulted in the number twenty-four—neither one more nor one less—and this repeated in many families belonging to the same sub-order but otherwise only remotely related to one another. Three years ago, when dealing with the affinities of the flat-fishes, Pleuronectidæ, I was struck by the discovery that, in the unquestionably least specialised genus, Psettodes, the vertebræ are twenty-four in number, the other known genera having from twenty-eight to sixty-five, and that the numbers increased along the most probable lines of evolution. A consideration of other families, and of the fossil forms in which the number of vertebræ has been ascertained, soon convinced me that this rule also applies to them, and that the order of evolution had in every case to be reversed from that assumed by Prof. Jordan, whose interpretation I had previously accepted as correct. As a result of my investigation into this question I believe that the frequent occurrence of twenty-four vertebræ is due to the original Acanthopterygians having presented this number, that it has been retained in the more generalised members of the families which have branched off from them, and increased or, more seldom, reduced in the course of evolution.

The view which I entertained when first studying the Cichlids of Lake Tanganyika must be abandoned, and the direction of the supposed lines of evolution reversed, together with the signification given by me to the characters of increased number of dorsal and anal rays, or of multiple lateral lines which go more or less hand in hand with the increase in the vertebral segments. I must therefore repudiate the statement, first made by me in describing some of the new genera discovered by Mr. Moore in Lake Tanganyika, that they show features of generalisation, the contrary being the case. This has been shown by Dr. J. Pellegrin, who has recently published a monograph of the whole family Cichlidæ, in which he has very ably dealt with the question of the interrelation of the various genera from the phylogenetic point of view.

Two theories have lately been put forward as to the origin of the African Cichlids.

According to Mr. Moore, to whom we owe the discovery of so many new forms in Lake Tanganyika, the Cichlids are of marine origin, and penetrated into a hypothetical Central African sea in præ-Tertiary times. But as no Perciform fish of any sort is known earlier than the Upper Cretaceous, and no Perch, in the widest sense, before the Lower Eocene (Prolates), the possible existence at that remote time of so specialised a type of Perches as the Cichlids is absolutely contrary to palæontological evidence. Further, such an explanation is unsupported by any geological data, no trace of Jurassic or Cretaceous deposits having been found on the plateau of Central Africa, notwithstanding much search over a considerable portion of the Congo State. It is impossible to imagine that such a sea could have existed without leaving any sedimentary deposits whilst its relics were being preserved in Lake Tanganyika. Besides, the distinguished Belgian geologist, Prof. J. Cornet, who has paid special attention to this question, and has himself surveyed a considerable part of the territory of the Congo State, regards the Tanganyika as by no means a very ancient lake, its formation not dating back beyond Miocene times. I may also here point out that Mr. Moore's interpretation of the affinities of the so-called "halolimnic" Mollusca has not received any support from those best able to judge of its merits. Mr. E. A. Smith, from the recent conchological, and Mr. Huddleston, from the palæontological point of view, have recently discussed his conclusions, with which they are unable to agree. I need hardly add that the discovery since the publication of the "Tanganyika Problem" of the Medusa *Limnocnida tanganicae* in Lake Victoria has dealt a further blow to Mr. Moore's theory.

As regards the origin of this Medusa, recent palæontological discoveries afford a much more rational explanation of the presence in Tanganyika of a Cœlenterate of unquestionably marine derivation. The highly important finds of fossils between the Niger and Lake Chad by the English and French officers of the Boundary Commission, which have been reported upon by Prof. de Lapparent, Mr. Bullen Newton, and Dr. Bather, have conclusively established the existence of Middle Eocene marine deposits over the Western Soudan, and the Egyptian and Indian character of these fossils, as well as of others previously obtained in Cameroon and Somaliland, justifies the belief in a Lutetian (Middle Eocene) sea extending across the Soudan to India. In fact, as stated by Mr. Newton, the palæontological evidence seems to prove that the greater part of Africa above the equator was covered by sea during part of the Eocene period. On this sea retreating northwards, after the Lutetian period, Medusæ became land-locked and gradually adapted themselves to fresh water: they had not far to travel to find themselves in what are now the Nile lakes, and later, through the changes which Mr. Moore himself has shown to have taken place in the drainage of Lake Kivu, they were easily carried into the Tanganyika—probably at no very remote time—and maintained themselves to the present day. I understand that the Medusa reported from Bammaku, Upper Niger, in 1895, but still

undescribed, has been re-discovered by Budgett, and is now being studied. Should it prove to be related to the Tanganyika species, it would also have to be regarded as a relic of the same Eocene sea, and it would add further support to the very simple explanation which I have ventured to offer of a case which seemed so tremendously puzzling in our previous state of ignorance of the geological conditions of Africa between the equator and the tropic of cancer.

As explained by Prof. Cornet, Tanganyika has been until very recent times without an outlet. The Lukuga, which drains into the Congo, was only formed after Lake Kivu became, owing to volcanic eruption, a tributary of the Tanganyika through the Rusisi River. The greater or less salinity of the water of a lake without an outlet is a matter of course, and therefore Tanganyika was for a long time a salt lake. Its water is still, Mr. Moore says, somewhat salt. No wonder that the Cichlids, which elsewhere in Africa show no aversion to such conditions, and which somehow or other contrive to settle into isolated waters, should have been among the first inhabitants of the lake, where, without having to face competition with other types of fishes, they throve and became differentiated into a multitude of genera. When the hydrographical conditions changed and the water gradually lost its salinity, first on the surface and later at greater depths, an influx of other forms of fish-life (Polypterus, Characinids, Cyprinids, Silurids, &c.) penetrated into the lake, some from the Nile system through the Rusisi, others from the Congo up the Lukuga. This explains well enough the character of the Tanganyika fish-fauna. The Cichlids, the oldest inhabitants of the lake, nearly all belong to endemic species, many of which constitute genera represented nowhere else; whilst the fishes of other families, later immigrants, all belong to widely distributed genera, and several of them even to species also found either in the Nile or in the Congo, or in both these river-systems.

The other theory is that the Cichlids have originated as fresh-water fishes in Eocene times in America and have crossed the Atlantic by a bridge which then connected South America with Africa. This is the explanation given by Dr. Pellegrin. He admits that we have no indication of any near allies of these fishes before the Middle Eocene (Green-River beds of North America), and, basing his statement on the last edition of Prof. de Lapparent's "Traité de Géologie" (1900), he says it seems to be beyond doubt that during the Lutetian period, which immediately followed that at which the earliest Cichlids were known to live in the fresh waters of America, a vast continent extended between South America and Africa. Should this have really been the case, the question of the distribution of the Cichlids could be regarded as settled. But I cannot satisfy myself that there is any geological evidence to support this view.

This third hypothesis has this advantage over the two others, that it does not postulate any land-areas in late Eocene or Miocene times, for which there is at present no sufficient evidence, nor a præ-Tertiary and marine origin for the family Cichlidæ, which is wholly improbable and receives no support from palæontology.

On the other hand, it is undeniable that the hypothesis of a South Atlantic land communication in the Eocene has much in its favour, and when this is really established all difficulty in explaining the distribution of the Cichlidæ will have disappeared. In the meanwhile, to use an appropriate metaphor, we must not construct bridges without being sure of our points of attachment, otherwise they are liable to collapse as geological knowledge progresses.

THE MASTACEMBELIDÆ.—At present we are acquainted with thirty-eight species of Mastacembelus: fourteen from the Indo-Malay region, one from Syria and Mesopotamia, and twenty-three from Tropical Africa. The distribution of these fishes, the fossil remains of which are still unknown, has probably once been a continuous one, climatic and hydrographic conditions possibly accounting for the present discontinuity. We have no data from which to decide whether the Mastacembelids first appeared in Asia or in Africa, or simultaneously in both parts of the world, as is quite possible on the assumption that the family originated in the Eocene sea extending from the Western Soudan to India.

This concludes our review of the affinities and past history of the principal fresh-water types which characterise the present African fish-fauna. We have endeavoured to show that a Tertiary land connection between Africa and South America is not absolutely necessary to explain the many points of agreement between the fresh-water fishes of these two parts of the world, as has been postulated by many writers. Besides, there are still some who hold, as does Prof. G. Pfeffer—whose interesting essay on the zoogeographical conditions of South America, from the point of view of lower vertebrates, appeared after this Address had been written—that a former subuniversality of distribution will afford a solution to many of these problems without necessitating such a land-connection, as exemplified by the past distribution of the Pleurodiran Chelonians. In this review we have summarised many previous hypotheses and added a few, but in every case with a feeling of dissatisfaction, fully realising, as we do, the futility of speculations in the present state of the two great branches of knowledge, geology and palæontology, on which the solution of these questions must ultimately rest.

We may now pass on to the realm of facts, and survey in the briefest manner the waters of the great continent as they appear after the many discoveries which have of late so greatly increased our knowledge of the African fishes.

In the present state of our knowledge of the fresh-water fishes Africa may be divided into five sub-regions, the discussion of the further subdivision of which would exceed the limits of this Address:—

(1) The North-Western Sub-region, or Barbary, and the Northern Sahara, properly forming part of the Palæarctic region.

(2) The Western-Central Sub-region, with all the great rivers and lakes, extending to the Nile Delta and the mouth of the Zambesi, for which the term Megapotamian Sub-region has been suggested to me by Dr. Sclater.

(3) The Eastern Sub-region—Abyssinia, with the upper tributaries of the Blue Nile, and the countries east of the Rift Valley and north of the Zambesi.

(4) The Southern Sub-region—all the waters south of the Zambesi system.

(5) Madagascar.

The smaller islands of the Indian Ocean have a fresh-water fish-fauna so insignificant that they may be entirely neglected in a broad division of the African region.

I. THE NORTH-WESTERN SUB-REGION.

In its deficiency in rivers of permanent flow Barbary has much in common with South Africa, and these two parts of Africa in their fish-fauna present a somewhat analogous example to that on which the now exploded theory of bipolarity was founded. Swelling to foaming torrents in the rainy season or after a storm, reduced to series of pools connected by tiny streams at other times, the watercourses are evidently unsuited to fish-life; and it is not surprising that, apart from a certain number of forms adapted to live in stagnant, often strongly saline, waters, the fishes should be so few in kind. But they make an interesting assemblage, in which it is easy to discover forms unmistakably suggestive of the præ-Pliocene times when the sea had not burst through the Straits of Gibraltar, mixed with others of decidedly Africo-Indian or Oriental affinities.

The number of species from inland waters, whether fresh or salt, hitherto recorded from this part of Africa, amounts to thirty or thirty-one only. Of these thirteen are Cyprinids, which may all be regarded as of northern or eastern immigration. Four of the Barbels show European affinities, one of them being found also in Spain, whilst the seven others belong to a section of the genus largely represented in Southern Asia and East Africa, but only known in West Africa from Cameroon. A species of Varicorhinus, recently discovered in Morocco, has similar affinities, the genus being known from South-Western Asia, Abyssinia, and Lake Tanganyika. A small somewhat aberrant species of the South-Western Asian genus Phoxinellus has been described from the Algerian Sahara, whilst an Alburnus from the Tell (originally placed in the genus Leuciscus) is also the sole representative in Africa of a genus inhabiting Europe north of the Pyrenees and

Alps and South-Western Asia. With two exceptions, all the Cyprinids are confined to the northern watershed of the Atlas, in which varieties of our River Trout and our Stickleback also occur; but *Barbus callensis* and the Phoxinellus occur also in the Algerian and Tunisian Sahara, showing that, as in other groups of animals, no sharp delimitation can be drawn between the Palæarctic and Æthiopian regions of Barbary.

Of three Cyprinodonts one, from the high plateaux, inhabits also Spain; another, more generally distributed, is known from Sicily, Syria, and North-East Africa; whilst the third, remarkable for the absence of ventral fins, is monotypic of a genus named Tellia—a misnomer, as it is not found in the Tell, but on the high plateaux of Algeria, at altitudes of from 2000 to 3000 feet, not 8000, as stated by Danbeck.

Three Cichlids are known from the Northern Sahara, one, a Tilapia, being restricted to Eastern Algeria and Tunisia, whilst the two others, a Hemichromis and a Tilapia, extend to Lower Egypt, and are besides widely distributed in Tropical Africa. The Cichlids, along with the Cyprinodon, the Barbus, and the Phoxinellus mentioned above, are often ejected by artesian wells, and the fact has given rise to much discussion. The latest investigator of this phenomenon, the distinguished engineer, M. George Rolland, confirms the opinion, expressed by the late Sir Lambert Playfair and M. Letourneux in 1871, that these fishes normally live and breed in the lakes and wells exposed to air and light, and that their presence in the underground sheets of water with which the lakes communicate is merely an episode, and as it were an incident in the voyages which they undertake from one opening to the other. There is therefore no justification for the term "realm of the Trogloichthydæ" which has been proposed by Dambeck for North-West Africa.

The other fishes which complete the list are of direct marine derivation, as the anadromous Shad and the catadromous Eel and Grey Mullets, or such as have recently adapted themselves to permanent existence in fresh water, like the Syngnathus discovered by Sir L. Playfair, the Atherina, which occurs also in various fresh-water or brackish lakes in Southern Europe and Egypt and in the Caspian Sea, two Gobies and a Blenny, the latter being also known from fresh waters in the South of France and in Italy. The occurrence of an otherwise strictly marine species of Blenniids (*Cristiceps argentatus*) in the fountain of Ain Malakoff, in the high plateaux of Algeria, rests on the testimony of a naturalist of Algiers and needs confirmation.

II. THE MEGAPOTAMIAN SUB-REGION.

The Nile, the Niger, the Gambia and the Senegal, the Congo, and the Zambesi, with their numerous Mormyrids, Characinids, Silurids, and Cichlids, have much the same general character, which points to many of the generic types having radiated from a common centre of origin, no doubt in those great central lakes which are believed to have existed in Middle Tertiary times. Lake Chad, the ichthyic fauna of which was until quite recently unknown, represents the dwindling remains of a larger basin which communicated until comparatively recent times with both the eastern and western river-systems, thus accounting for the great resemblance between the fishes of the Nile and those of the rivers of the Atlantic watershed north of the Cameroons, 46 species out of 101 known from the Nile (without the great lakes by which it is now fed) being also found in the Niger, the Senegal, or the Gambia, or in all three, and most of these have been recently found in Lake Chad and the rivers emptying into it. The collection made in Lake Chad by Captain Gosling, and sent by him to the British Museum, contains representatives of twenty-four species, all of which were previously known from both the Nile and the Niger, thus strikingly confirming conclusions arrived at from a study of the fauna of those two river-systems. Collections sent to the Paris Museum by the Chevalier and Decorse Mission, and worked out by Dr. Pellegrin, add twenty-five species to the above number, two described as new, two Nilotic, eight West African, five Congolese, the rest being common to the eastern and western river-systems. The Congo differs more considerably, and must therefore have been separated from the Nile-Chad-Niger for a longer period, only 15 out of its 265 species (excluding the Tanganyika) occurring also in the Nile, and eleven in the Chad. When we reach the district of the sources of the Congo, the so-called Katanga district, we find a mixture of Congo and Zambesi forms, which points to a former reversal of the drainage of parts of the elevated dividing range. Lake Mwero belongs to this district; although so near to Lake Tanganyika, it has no fish in common with it except a few of very wide distribution. Lake Bangweolo, also in the same district, is said to swarm with fishes, Silurids and Cichlids especially, but they have never been collected. The Zambesi, so far as it has been explored at present, is the poorest in fishes of the great rivers, and it differs from the others in one important point—the absence of the Polypteridæ. The great lakes differ considerably in their fishes from the river-systems into which they drain.

As pointed out eleven years ago by Prof. Gregory, the system of the head waters of the Nile must have been very differently arranged in times geologically quite recent. This is proved by what we know of the great lakes north of Tanganyika. Thus, of the species known from Lake Victoria, barely one-fourth occur also in the Nile, the rest being mostly endemic; whilst Lake Rudolf, which has now no communication with the Nile, has four-fifths of its species in common with that system. Lakes Albert and Albert Edward are very insufficiently explored and have only yielded a few species, one-half of which are Nilotic. Two fishes, Cyprinids, are all we know from Lake Baringo, one being a widely distributed Nile species, the other an East African. We must conclude from these data that Lake Victoria has long been isolated, whilst Lake Rudolf has until very recently been in communication with the Nile.

Lake Tsana, which is now the source of the Blue Nile, has recently yielded a large collection of fishes, showing a great variety of Cyprinids, either endemic or identical with species occurring in the eastern watershed, and closely allied to those of Palestine, but with no special Nile affinities. The discovery of a Loach (Nemachilus), the first known from Africa, points to an immigration from the Jordan, probably through the old Erythrean Valley. The only species which Lake Tsana has in common with the Nile (*Tilapia nilotica*) occurs also in the Hawash and in the Jordan.

From the vastly increased information we now possess of the fishes of the Nile-system, we are justified in believing in great changes in the hydrography of this part of Africa. The fishes of Lake Tsana would support Prof. Gregory's conclusion as to a communication with the Jordan through a river running along what is now the Red Sea, whilst those of the Lower Nile point to a direct communication between the latter and the Jordan, as advocated by Prof. Hull, migrations along two distinct channels having taken place at a time when the Mediterranean did not extend so far to the east as it does at present, and the Indian Ocean had not penetrated into the Erythrean Valley. A better knowledge of the fishes of Egypt has disposed of Prof. Gregory's arguments against a former communication between the Lower Nile and the Jordan.

The Nile in its widest sense, but without the great lakes, has 101 species, not including those that enter the sea: twenty-seven do not extend north of Khartoum, whilst only six are restricted to the river below the First Cataract. The most important additions made since Dr. Günther's account of them in "Petherick's Travels" are several Mormyrs, Barbus, and Synodontis, three Cichlids, a Xenomystus, a Nannæthiops, a Discognathus, a Barilius, a Chiloglanis, a Fundulus, an Eleotris, and the remarkable genera Physailia, Andersonia, and Cromeria, the latter the type of a new family.

Thanks to the collections made by Sir Harry Johnston and Col. Delmé Radcliffe, with the help of Mr. Doggett, and by M. Alluaud, supplementing those of Dr. Fischer, we may now draw up a list of twenty-five species from Lake Victoria. The comparative scarcity of animal and vegetable life in this great lake perhaps precludes expectation of a great increase in the number of species in the course of further exploration. Most of the species are endemic, and among the most remarkable types may be mentioned a Discognathus, a Mastacembelus (probably the

fish noticed by Grant as a Stickleback), and a peculiar genus of Cichlids, Astatoreochromis. No Polypterus has yet been found.

Lakes Albert and Albert Edward, recently visited by Mr. Moore, have furnished examples of nine species, mostly Nilotic in character, the most interesting being a Petrochromis, on account of its close affinity to a Tanganyika species.

Lake Rudolf, as stated above, differs hardly from the Upper Nile, only three of its sixteen species being indicative of immigration from the East. Not a single form is endemic.

The Senegal must have been very thoroughly explored by Dr. Steindachner thirty-five years ago, as a large collection made a few years since by the late M. Delhez has not resulted in a single addition to the list of species. The Gambia, on the other hand, is now much better known than it was, thanks to the two visits of the late Mr. Budgett, to whom we owe the discovery of two species. But it is the Niger which, through the collections made by Dr. C. Christy, the late Captain G. F. Abadie, Mr. Budgett, and especially Dr. Ansorge, has been productive of the most important additions to our knowledge. The most striking discoveries are the type of a new family, Phractolæmus, since re-discovered in the Ubanghi, and Polycentropsis, the first representative of the Nandidæ in Africa. Leaving aside species entering the sea, we now know fifty-four species from the Senegal, forty-one from the Gambia, and ninety-six from the Niger, the lower course of the latter being the most productive. A remarkable feature of these rivers is the comparative paucity of Cyprinids, and the total absence in the first two of the genus Barbus, which also appears to be absent from the Chad basin.

Our knowledge of the piscine inhabitants of the rivers flowing into the Atlantic between the mouths of the Gambia and of the Niger has also made considerable progress. The fishes of Liberia, collected by Dr. Büttikofer, have been described by Dr. Steindachner, and those of the Gold Coast, collected by the late Mr. R. B. Walker, have been reported upon by Dr. Günther. Sixty-seven species are on record from this district, twenty-four of them being endemic.

Further South, North Cameroon has yielded several additions, for a knowledge of which we are indebted to Dr. Lönnberg, whilst South Cameroon, together with the Gaboon district, has been diligently explored by Mr. G. L. Bates, with the result that a great number of new species have been brought to light. This part of Africa is specially interesting from the fact that its rivers interlock with the head waters of the Sanga, which belongs to the Congo basin, and, the fishes being mostly the same in both watersheds, in that district, a sort of passage is established between the Gaboon and Congo faunas. Among the most remarkable forms discovered by Mr. Bates we may mention the genera Microsynodontis, Allabenchelys, and Procatopus. Since Dr. Sauvage reported, twenty-five years ago, on the fishes of the Ogowé, a small collection has been made by the late Miss Kingsley, and described by Dr. Günther, and a number of new species have been characterised by Dr. Pellegrin. The number of species now known from this part of Africa amounts to eighty-seven for South Cameroon and the Gaboon, and fifty-four for the Ogowé. Very curiously, among them we miss Polypterus and Calamichthys, which occur in the Lower Niger and Old Calabar, and again in the Chiloango—a remarkable instance of discontinuous distribution, which cannot be accounted for by physical conditions, so far as we are acquainted with them.

The Congo system (exclusive of Lake Tanganyika), from which only about ninety species of fishes were known ten years ago, proves to be far richer than any other, for, incompletely explored as it still is, it has already furnished examples of 265 species, forty-five of which have been added since the publication of the work "Les Poissons du Bassin du Congo" in 1901. In fact, every collection made even in its most accessible parts adds new species to the list, and many of its rivers have never yet been fished for scientific purposes. No doubt we do not know more than two-thirds of the fishes of the Congo. The riches in Mormyrids, Characinids, Silurids, Cichlids, Mastacembelids, is something surprising, not only in the number of species, but also in their extraordinary variety of structure; and as many as seven species of Polypterids, out of the eleven that are now known, occur in this river-system. With the exception of the Cromeriidæ and Nandidæ, all the families known from the sub-region have representatives in the Congo.

Lake Tanganyika, now forming part of the same hydrographic system, has a somewhat different fauna, consisting mainly of Cichlids, to which we have specially alluded in an earlier part of this Address. But there are, in addition, a number of Silurids and Cyprinids, a few Mastacembelids and Characinids, a Cyprinodont, and a Polypterus. The latter belongs to a species otherwise restricted to the Congo, and of the four Characinids two are Congo and two are Nile forms. The total number of Tanganyikan species of fishes amounts to eighty-five, but, no doubt, many more await discovery. As I pointed out in reporting on Mr. Moore's second collection, I have reason to think that we do not know more than half the species of fishes inhabiting this extraordinary lake. The collection which has just been brought home by Mr. Cunnington will greatly add to our knowledge. I may here mention that Mormyrids, which were believed to be absent from Tanganyika, are therein represented by two species.

Lake Rukwa has recently been explored by Dr. Fülleborn, but the fishes, which have been referred to eleven species, belonging to widely distributed genera, have not been studied with a sufficient comparison-material: they appear to be mostly endemic forms.

Lake Mwero has representatives of fourteen species, five of which are endemic, the remainder being found also in the Congo or in the Zambesi, or in both.

The Zambesi, so far as we know it—and its upper parts have scarcely been explored—appears rather poor in fishes, only forty-one species having been recorded. All the genera are also represented in the Congo and in the Nile. Seven of the Zambesi species occur also in Lake Nyassa and the Upper Shiré, whilst in the present state of our knowledge twenty-seven species, mostly Cichlids, may be regarded as endemic to the lake and the Upper Shiré. It is perfectly clear, however, that Lake Nyassa differs far less from the Zambesi than Tanganyika does from the Nile or Congo; and, although the Cichlids are likewise represented by some remarkable genera, they cannot compare for variety with the other great lake the fauna of which has been such a surprise. Both the Zambesi and Lake Nyassa lack representatives of the Polypteridæ.

About forty-five years ago a collection of fishes was made in Lake Ngami, and twelve species were described in a very unsatisfactory manner by the late Count F. de Castelnau; unfortunately the types of these species are lost, and it is difficult to form an idea of their affinities. We know, however, that the lake, which is now rapidly drying up, was then inhabited by a Mormyr, a Clarias, a Characinid, and several Cichlids.

The rivers of Angola have been but imperfectly explored. They have yielded a number of Cyprinids and Cichlids, a few Silurids, Mormyrids, and Cyprinodontids, and the type of the remarkable genus Kneria, the second species of which inhabits East Africa.

III. THE EASTERN SUB-REGION.

As was mentioned in the beginning of this Address, latitude goes for little in the distribution of fish-life. This is proved by the very marked difference in general character of the fish-faunas of Abyssinia and Africa east of the great Rift Valley as compared to the Nile and Central and West Africa. No Polypterids or Mastacembelids, few Mormyrids, Characinids, and Cichlids, but a great number of Cyprinids, mostly Barbus, characterise this sub-region. Omitting catadromous forms, the list of fishes consists of one Lepidosirenid, six Mormyrids, eight Characinids, seventy Cyprinids, twenty Silurids, one Kneriid, six Cyprinodontids, and seven Cichlids.

Lake Tsana, with the upper affluents of the Blue Nile, differs very strikingly in its fishes from the Nile, with which it has only two species in common, a Silurid (*Bagrus docmac*), and a widely distributed Cichlid (*Tilapia nilotica*), which occurs also in the Hawash and in

Palestine. Nearly all the fishes are Cyprinids, mostly of the genus Barbus, which bear close affinity to Syrian types, as does also the recently discovered Loach (*Nemachilus abyssinicus*), so far the only known African representative of that Europæo-Asiatic group. The single species of the Cyprinid genus Varicorhinus is also suggestive of South-Western Asia, although a second African species inhabits Lake Tanganyika, and a third has lately been discovered in Morocco. Another Cyprinid genus, Discognathus, which is widely distributed over Southern Asia, from Syria and Aden to Burma, is represented by two species, whilst others are known from Abyssinia and East Africa (Gallaland, Kenya, and Kilimandjaro districts), and one each from the Nile and Lake Victoria. A remarkable negative feature is the absence, as in Syria, of Labeo, a genus abundantly represented in the Nile, Senegal, Niger, Congo, and Zambesi, and India, and more scantily in East and South Africa. It is a suggestive fact, tending to show that, somehow or other, Lake Tsana has only comparatively lately been in communication with the Nile, that the Varicorhinus and several of the Barbus are common to this lake and to some of the rivers of the eastern watershed; whilst not one of the Cyprinids occurs also in the Nile. The main stream of the Blue Nile has only been explored up to Rosaires, but the fishes obtained in that part of the river do not in any way differ from those of the Upper Nile.

The chief character of the rivers east of the Rift Valley is, as already stated, the number of species of Barbus. The Cyprinids are further represented by a few Labeo and Discognathus, by a Neobola, and by the only African representative of the Indo-Malay genus Rasbora. The Mormyrids are represented by six species only. The few Characinids belong to the genus Alestes and to its near allies Micralestes and Petersius. Of the twenty Silurids, some are widely distributed species, others are common to the Nile or to the Zambesi, whilst among the species with a restricted habitat we note a Physailia, two Bagrus, two Amphilius, a Synodontis, and two Chiloglanis—altogether a poor series as compared with other districts of Tropical Africa—and not a single autochthonous genus. A species of the remarkable genus Kneria, a few Cyprinodontids, and a few Cichlids of the genus Tilapia complete what is for a district of that extent, well watered and within the tropics, a very meagre list.

IV. THE SOUTHERN SUB-REGION.

Africa south of the Zambesi system has a poor fresh-water fish-fauna, but this is easily accounted for by the intermittent character of most of its rivers. The list I have drawn up from available data includes only fifty species, seven of which are partly marine. When discussing the distribution of the South African fresh-water fishes eight years ago Prof. Max Weber compiled a list of sixty-four species; but this included a number of truly marine forms, occurring only in estuaries, besides a few of very doubtful determination, which I am obliged to leave out. The majority of the exclusively fresh-water fishes are Cyprinids, viz. seventeen Barbus and three Labeo. Characinids are represented by the widely distributed *Hydrocyon lineatus*, which occurs in the Limpopo, and the newly discovered *Alestes natalensis*, from near Durban. Three Clarias, an Eutropius, a Gephyroglanis, and a Galeichthys, the latter semi-marine, represent the Silurids. The two Galaxias, as distinguished by Castelnau, the most remarkable type of the South African fish-fauna, and the two Anabas, are confined to the south-western district of Cape Colony. A Cyprinodontid of the genus Fundulus has been described from False Bay. Four Gobies and five Cichlids of the genera Hemichromis, Paratilapia, and Tilapia complete the list.

Poor as it is in fishes, the south-western district—the *Erica or Protea district* of Max Weber—derives a special character from the presence of the genera Galaxias and Anabas. The western district is also poor, and has only representatives of three families: Cyprinids, Silurids, and Cichlids; whilst the eastern district, from the Limpopo system and the tributaries of the Orange River to Natal, is the richest, two families, Characinids and Gobiids, being represented, in addition to the three above named. The recent discovery in the Vaal River of a Gephyroglanis, a Silurid genus otherwise known only from the Congo and Ogowé, deserves notice.

Whether the subterranean reservoirs of the Kalahari are inhabited by fishes, as is the case in the Northern Sahara, is still unknown.

Excepting such forms as are believed to have been directly derived from marine types, there is every reason to regard the piscine inhabitants of the fresh waters of South Africa as comparatively recent immigrants from the North.

V. MADAGASCAR.

It is extremely remarkable that this great island, which in most groups of animals shows so many striking features, should in its fish-fauna be one of the most insignificant districts in the whole world. For, if we exclude the numerous Grey Mullets and Gobies, and a few Perches of the genera Kuhlia and Ambassis, which live partly in the sea, and probably mostly breed in salt water, the truly fresh-water fish-fauna is reduced to sixteen species—viz., two Silurids, two Cyprinodontids, one Atherinid, four Cichlids, and seven Gobiids, the latter, no doubt, recent immigrants from the sea. The Silurids belong to two distinct genera, Læmonema, allied to the African Chrysichthys, first discovered in Mauritius, and Ancharius, allied to the marine or semi-marine Arius, and, perhaps, also entering the sea. Of the four Cichlids two belong to a very distinct autochthonous genus, Paretroplus, whilst the two others are respectively referred to the African genera Tilapia and Paratilapia. The two Cyprinodontids belong to the widely distributed genus Haplochilus.

In concluding this sketch, whilst looking back with satisfaction upon the rapid progress which African ichthyology has lately made, and expressing our gratitude to the Governments, institutions, and collectors to whom we owe this progress, we cannot abstain from pointing out how much remains to be done. All the great lakes are insufficiently explored, and Bangweolo has never been fished for scientific purposes, whilst within the limits of this colony an extensive collection from the Upper Zambesi is still a desideratum, and Lake Ngami is drying up without any of its fishes having been secured for study. The fishes of the Congo above Stanley Falls, and of many of its northern and all of its southern tributaries, are still unknown. But it is gratifying to observe the ever-growing interest in this hitherto somewhat neglected branch of zoology, and I may express the hope that the next decade will be productive of even greater results than have been achieved within the last.

NOTES.

WE regret to see the announcement of the death of Prof. Jules Oppert, professor of Assyrian philology and archæology at the Collège de France, renowned for his contributions to astronomical chronology and his works on Chaldea and Assyria.

THE Berlin correspondent of the *Times* announces the death, at seventy-six years of age, of Prof. Franz Reuleaux, who, as author of a number of engineering works and director of the Berlin Industrial Institute, rendered good service to the development of practical and scientific engineering in Germany.

NEW ORLEANS has been suffering from a serious outbreak of yellow fever, but there are now signs that the health authorities are getting the disease well in hand. Up to the end of last week, that is, a period of about four weeks, more than 1000 cases and 171 deaths had been recorded. It is believed that the fever was introduced into the city through fruit vessels arriving between June 1 and June 15 from Central America. All patients have been screened from mosquitoes, and there must now be little danger of infection from them.

THE returns of births and deaths recently issued by the Registrar-General, while in some respects satisfactory, in one are of a disquieting nature. This is with reference to

the birth-rate, which during the last few years has steadily been declining, and has now reached the lowest figure on record, viz. 27·0 per 1000 for London and 29·2 per 1000 for seventy-five large towns. There must come a time, if this decline continues, when the deaths will exceed the births, and our population will decrease—a serious catastrophe for the nation. Were it not for a diminishing death-rate, particularly among infants, this contingency would already have come to pass. It is especially among the middle and upper classes that the birth-rate has declined, partly owing to selfishness and love of pleasure, but also partly due to the strenuousness of the conditions of modern life.

SIR J. CRICHTON-BROWNE delivered his presidential address to the conference of the Sanitary Inspectors' Association on August 17. He dealt with the problem of the sanatorium treatment of consumption, and expressed the opinion that splendid results had been obtained by it, and that Dr. Maudsley at the British Medical Association meeting (see NATURE, August 3, p. 331) had spoken too despondently about it, which was to be regretted, as it might tend to check a movement of great promise. He proceeded to consider the question of physical deterioration, and then dealt at length with the housing problem, and pointed out the advantages from a health point of view of country life as compared with town life. That the townsman was shorter lived than the countryman was, he said, incontrovertible.

THE relief ship *Terra Nova* returned to Tromsö on August 10 with the members of the Ziegler North Polar Expedition on board. Mr. A. Fiala, the leader of the expedition, landed at Hull on Tuesday on his way to the United States, and gave a representative of Reuter's Agency an account of the experiences of the expedition. The *America*, with the members of the expedition on board, left Vardo on July 10, 1903. At the end of August the vessel reached Teplitz Bay, Crown Prince Rudolf Island, the most northerly harbour in Franz Josef Land, where magnetic and astronomical stations were erected. The ship was frozen in during October, and was wrecked by great ice pressure in the following month, so that the entire party had to be taken ashore on sledges. In January, 1904, during a gale, all the old ice in Teplitz Bay, with several miles of the glacier face, were broken and carried away, and with the bay ice disappeared all that was left of the *America*. Three attempts were made to reach the Pole by sledges, but the highest point attained was 82° 13′ north latitude. Mr. Fiala states that although the avowed purpose of the expedition—to reach the North Pole—was unsuccessful, the members have brought back data which should prove of scientific value, and have explored and surveyed the archipelago from Crown Prince Rudolf Land to Cape Flora, discovering four new channels and three large islands.

THE fifteenth International Congress of Americanists will be held at Quebec on September 10–15, 1906. The work of the congress will be concerned with the indigenous races of America, their origin, geographical distribution, history, physical characters, languages, civilisation, mythology, religion, manners, and customs; indigenous monuments and archæology of America; history of the discovery and European occupation of the New World. The president of the committee of organisation of the congress is Dr. Robert Bell, F.R.S., director of the Geological Survey of Canada, and the general secretary is Dr. N. E. Dionne, Quebec, Canada.

TRIALS of a system of signalling by bells under water, which has been developed by the Submarine Signalling Company, of Boston, U.S.A., were made by the Trinity House authorities on August 11. This invention, which was described in NATURE of April 20 (vol. lxxi. p. 595), has been used experimentally by the United States Lighthouse Board at several of their light stations during the past few years; it has also been adopted by the Canadian Government as an aid to navigation in the St. Lawrence. For the purpose of these trials the North Goodwin lightship was fitted with a submarine bell, and the Trinity steamship *Irene* with the necessary sound-receiving apparatus. At distances of from three to five miles the signals given by the bell were distinctly heard, and the direction whence they emanated could be readily noted.

MR. C. R. CROSBY has favoured us with a copy of a catalogue of the North American spiders of the group Erigoneæ, contributed by him to the *Proceedings of the Philadelphia Academy*.

THE fourth and final part of vol. xxv. of *Notes from the Leyden Museum* contains, among other papers, the concluding portion of the preliminary description, by Miss C. M. L. Popta, of new fishes collected in Borneo by Dr. Nieuwenhuis, and likewise one by Dr. Lidth de Jeudi on new Bornean lizards.

WE have received the report of the Trivandrum Museum and Public Gardens for 1903–4, which is signed by the new director, Major F. W. Dawson. In addition to statements in regard to the condition and progress of the establishment, some interesting details are given with regard to the amount of food consumed by some of the reptiles in the gardens; and Mr. Lydekker's paper, in the *Journal of the Bombay Natural History Society*, on certain dolphins recently taken on the Travancore coast is reproduced in full.

THE report of the Field Columbian Museum, Chicago, for the period 1903–4 contains reproductions from photographs of some of the chief objects of interest added during the year. The wide scope of the exhibits, and the beauty and thoroughness of the installation, are very noteworthy. Among the exhibits special reference may be made to one of a group of wild duck being stalked by a lynx, and to a second illustrating the ingredients entering into the composition of curry-powder. In the latter no less than thirty-one trays of distinct specimens are shown.

IN the course of last week's notes, reference was made (p. 385) to the web-making ants of the genus Œcophylla. In the latest issue (August 1) of *Biologisches Centralblatt* Dr. F. Doflein gives a detailed description of the habits of *Œ. smaragdina*, a species widely distributed in the Oriental region, accompanied by original sketches of the ants and their larvæ at work. When the edges of a leaf are to be joined, or when a rift appears in the nest, a small company of the workers place themselves in a line across the fissure, holding on to the one edge with their mandibles and to the other with their legs, which are stretched backwards to their furthest extent, and then with a united pull drag the two edges into contact. A second party then comes, and trims and fits the edges until they meet exactly, while finally comes a third party, each member of which carries a larva in its jaws. The larvæ, being put to work, immediately spin a "criss-cross" web by means of which the two edges of the leaf are firmly united.—In another paper in the same issue Mr. F. E. Zierler, of Dorpat, discusses the molar dentition of the fossil Suidæ in connection with their phylogeny. Apparently the author makes no reference to the theory that the crown-structure of the suilline molar is a degradation from the selenodont type.

AN interesting contribution to the history of the steam-engine is published in the *Engineer* of August 11 in the form of particulars of some old prints unearthed at the British Museum. One of the most interesting of these, engraved by Sutton Nicholls and bearing the date 1725, is that illustrated in the accompanying figure, reduced from one of the illustrations in our contemporary. The engraved part measures 13¾ inches by 12¾ inches, and on either side in letterpress appears a detailed description. The print is believed to be unique, and in point of date is second only in importance to the Dudley Castle steam-engine print of 1712, preserved in the Birmingham Free Library. It resembles the drawings of the Newcomen engine at the colliery at Griff, in Warwickshire, erected in 1722. Several changes in the mechanical details from the Dudley Castle engine may be noted. The boiler is fed with a portion of the hot water coming from the bottom of the cylinder, so that a date is fixed for this advance in economy. There are also two gauge-cocks instead of one, so that both high and low water would be indicated. Reproductions are also given in the same article of copper plates of the Newcomen engine erected at Passy, near

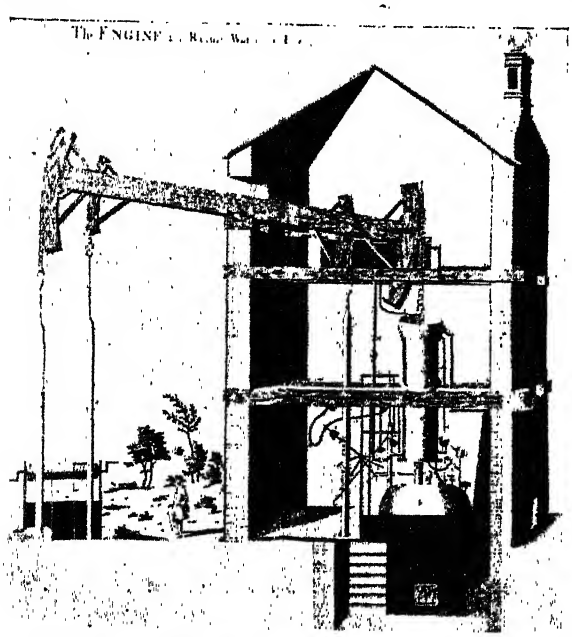

FIG. 1.—A mospheric Steam Engine, 1725 From the *Engineer*.

Paris, in 1726, which was copied from that at Griff Colliery. The first Newcomen engine on the Continent was, however, that put down in 1722 at Cassel by Joseph Emanuel Fischer von Erlach, who ordered at the same time in England a similar engine for draining a mine at Königsberg, in Hungary. This was completed in 1724 by one Isaac Potter from Durham, who was in consequence looked upon as the inventor.

THE *Journal of the Röntgen Society* for July (ii., No. 5) contains reports of meetings of the society and of the Röntgen Congress at Berlin, and various papers, notes, &c., as well as three plates of excellent radiograms and a portrait of the president, Mr. Wilson Noble.

THE *Journal of the Royal Sanitary Institute* for August (xxvi., No. 7) contains a valuable discussion on sanatoria for consumptives, opened by Mr. Edwin T. Hall, and an interesting paper by Dr. Rideal on the sterilisation of sewage effluents, with special reference to oysters and other shell-fish, and to watercress beds.

WE have received a copy of Messrs. Merck's annual report for 1904 on the advancements of pharmaceutical chemistry and therapeutics during that year. It contains a wealth of information, and should be in the hands of every medical practitioner and pharmaceutical chemist who wishes to keep abreast of modern work and progress.

THE Annual Report and Transactions of the Manchester Microscopical Society for 1904 has just reached us. The society is evidently in a flourishing condition, and several of the contributed papers are of interest, particularly those by Prof. Hickson, the president, on micro-organisms associated with disease, and by Mr. Gillanders on arboreal insects, with two illustrative plates.

WITH reference to a note on the Leishman-Donovan body or parasite which appeared in these columns (June 15, p. 157), Lieut. Christophers, I.M.S., writes pointing out that his researches on the development of flagellated forms antedated those of Leishman, but that Capt. Rogers, I.M.S., was the first discoverer of the metamorphosis. The latter fact was noted in NATURE (vol. lxx. p. 534).

PROF. F. RAMALEY contributes an account of the examination of certain foliaceous cotyledons to the *University of Colorado Studies* (vol. ii., part iv.). The anatomical structure of the cotyledons of several species of tropical plants was examined for comparison with the structure of the ordinary leaves.

A SIMPLE piece of apparatus, called a pinometer, for connecting both ends of a plant, cut as for a root-pressure experiment, has been devised and is described by Dr. O. V. Darbishire in the *Botanical Gazette* (May). The object of the pinometer, which is well adapted to ordinary class work, is to enable the experimentalist to study at one time both the suction force of transpiration and root-pressure. For research purposes the author is elaborating a more complex and precise form of the instrument.

SIR JOSEPH HOOKER continues his epitome of the British Indian species of Impatiens in No. 2, vol. iv., of the *Records of the Botanical Survey of India*. This includes a list of eastern Himalayan plants, of which the chief centre is Sikkim, and fifty species from Burma of which three-quarters are endemic. In addition to the new species which, as Sir Joseph Hooker expects, still await discovery in Sikkim and Burma, there is great need for collecting better material, more especially good specimens of the flowers and of separate parts of the flowers.

THE *Trinidad Bulletin* for July contains an account of the results obtained during the first year in manurial experiments with cacao plants on the Brasso Estate. Mr. E. H. Cunningham-Craig contributes some geological notes on soils in Trinidad to serve as an explanation of the geological maps that have been produced, and also to furnish a guide to cacao planters of the value and probable manurial requirements of the various soils. Mr. C. W. Meaden has an article on parasites in cattle and poultry, giving a detailed account of the parasite *Strongylus micrurus*, with remarks on the methods of treatment. A report on various rubber plantations in the island is presented by Mr. W. Leslie.

MESSRS. R. AND J. BECK, LTD., have sent us a dark screen mounted in a convenient way for use in viewing the eclipse of the sun on August 30. If the sky is clear, a smoked or very dark glass will enable the progress of the partial eclipse to be followed in any part of our islands.

OUR ASTRONOMICAL COLUMN.

OBSERVATION OF JUPITER'S SEVENTH SATELLITE.—A telegram from Prof. Pickering to the Kiel Centralstelle announces that Prof. Albrecht has observed Jupiter's seventh satellite with the Crossley reflector. Observations were made on August 7, 8, and 9, and on the first named day the satellite's position in reference to Jupiter was as follows:—

G.M.T.	Position angle	Dist.
1905 Aug. 7 96 ...	289°·7 ...	54'·6

(Circular No. 78 Kiel Centralstelle).

COSMIC DUST OF SOLAR ORIGIN.—The hypothesis that certain terrestrial phenomena, *e.g.* magnetic storms and auroræ, are caused by the earth passing through denser portions of streams of finely divided gravitating matter ejected by the sun is discussed by Prof. Schaeberle in No. 4041 of the *Astronomische Nachrichten*. One of the greatest objections to this hypothesis appears to be that no regularity of period has been discovered for the ejections which would fit in with the observed data of the terrestrial phenomena. Prof. Schaeberle shows, however, that a largely irregular period affords fundamental evidence in favour of the hypothesis.

Both theory and observation lead to the conclusion that the ejective forces on the sun are very variable, and this would certainly mean that the initial velocities of the particles ejected would vary considerably. In a table he has prepared the author shows that particles ejected with an initial velocity of 376·76 miles per second would just reach the earth's orbit, the time taken being 64·6 days. An initial velocity of 381·78 miles per second would carry the particles to four times the earth's distance; their velocity on passing the earth's orbit would be 22·4 miles per second, whilst the time taken to reach the earth on the outward journey would be 29·7 days; 1003 days would elapse before they crossed the earth's orbit on the return journey. Particles ejected with a velocity of 382 miles per second would cross the earth's orbit with a velocity of 25·9 miles per second in 27·4 days, and would be carried to an infinite distance. Thus a very small change in the initial velocity at which the particles are ejected causes a very large change in the time taken to reach the earth, and therefore Prof. Schaeberle maintains that the irregularity of such phenomena is evidence in favour of the existence of such streams. He also discusses some cometary phenomena which, he considers, furnish the strongest evidence in favour of the hypothesis.

THE ORBIT OF γ CORONÆ BOREALIS.—The following elements for the binary system of γ Coronæ Borealis have been deduced by Mr. Doberck, of the Hong Kong Observatory, from all the available observations recorded since 1826:—

$\Omega = 113^\circ\ 20'$	$\gamma = 80^\circ\ 8'$	$P = 79{\cdot}63$ years
$\lambda = 254^\circ\ 55'$	$e = 0{\cdot}3589$	$T = 1839{\cdot}60$
	$a = 0''{\cdot}598$	

Mr. Doberck gives a table containing the results obtained by each observer, omitting those which are in any way doubtful (*Astronomische Nachrichten*, No. 4041).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 14.—M. Bouquet de la Grye in the chair.—The study of the solar atmosphere round the spots: H. **Deslandres.** The author explains in detail the method adopted by him for the study of the spectra of the sun-spots, the special lines selected being the K_1 and K_2 lines of calcium.—On the gases produced by actinium: A. **Debierne.** It has been shown by Ramsay and Soddy that solutions of radium salts give off detonating gas containing a very minute quantity of helium. The author has examined actinium salts from the same point of view, and has found that in this case also a mixture of hydrogen and oxygen is continuously evolved. Helium was found to be present in this gas, and in quantity comparable to that given by radium. By way of control, the experiments with a solution of radium bromide were repeated and the results of Ramsay and Soddy confirmed.—On the production of heavy liquids with the alkaline iodomercurates: M. **Duboin.** The compounds of mercuric iodide with potassium, sodium, lithium, and ammonium iodides have been prepared, and the densities of the heaviest solutions obtainable measured. Whilst Thoulet's liquid (solution of potassium iodomercurate) has a density of 3·196, the solution of the corresponding sodium salt has a density of 3·46, of lithium 3·28, and of ammonium 2·98. The sodium and lithium salts are therefore superior to the original solution proposed by Thoulet. They are soluble without decomposition in alcohol, and are suitable for the separation and determination of the density of minerals.—The pure culture of green plants in a confined atmosphere in presence of organic substances: M. **Molliard.** The results of the experiments show the possibility of the absorption and utilisation of glucose in sunlight by the plant, this absorption being increased when asparagine was also present in the solution.—The physiology of the placenta: MM. **Charrin** and **Goupil.**—On a toxic product extracted from the cerebral substance: A. **Marie.** The brain substance was brought into an emulsion with five times its weight of water, centrifugalised, and filtered, first through paper and finally through a Berkefeld filter. The liquid thus obtained showed distinctly toxic properties, the nervous system being especially affected.—On infectious anæmia in the horse: H. **Carré** and H. **Vallée.** Attention is directed to the state of latent infection exhibited by certain horses, apparently cured, and means given of detecting such cases. The results of the research are summarised in the form of practical instructions as to the best mode of dealing with an outbreak.—On the preparation of cholera toxin: MM. **Brau** and **Denier.**

THURSDAY, AUGUST 31, 1905.

BRITISH MOSSES.

The British Moss-Flora. By R. Braithwaite, M.D., F.L.S., &c. Pp. x + 315; 268; 274 + plates. (London: L. Reeve and Co., 1887 to 1905.)

WE offer to Dr. Braithwaite our most sincere congratulations on the completion of this work on his favourite class of plants. Begun, as regards publication, in 1880, it reached completion by the issue of the last part with index and supplement in May of this year, so that the course of publication has occupied a space of some quarter of a century. In the last number Dr. Braithwaite takes leave of his readers in a postscript in which he expresses his regret that he is unable to include the Sphagnaceæ in the work; but he finds that to study these again at the age of eighty-one, and to draw some twenty-five plates, would be hopeless. All lovers of mosses will share in this regret, at the same time remembering that they owe to Dr. Braithwaite an interesting monograph on the peat mosses of Europe and America, published in 1880. The author concludes the whole matter with a quotation of some lines (little known, we suspect) by Ehrhart, which are interesting as disclosing the mental attitude of the venerable author at the conclusion of his labours; they begin thus:—

> "Vernimm's und siehe die Wunder der Werke,
> Die, die Natur dir aufgestellt!
> Verkündigt Weisheit und Ordnung und Stärke
> Dir nicht den Herren; den Herren der Welt?"

The three volumes of Dr. Braithwaite's book are illustrated by 128 pages of plates, giving figures of every moss described, with enlarged designs of parts of the various species. Every one of these plates has been engraved from the drawings of the author himself, and together constitute a remarkable monument of his skill and industry. Indeed, the illustrations may be regarded as perhaps the most distinctive feature of the work. In some cases a whole page is devoted to a single species, as Schistostega, or to two species, as in the strange genus Buxbaumia; but generally four or more plants are dealt with in a single plate. So far as we have compared the figures of our author with nature, we have found his drawings accurate, and the magnified parts very valuable for the purposes of identification.

If we were inclined to be adversely critical on the plates, we should say that to some extent strength has been sacrificed to elegance. If you turn from the drawings of Braithwaite to the plates of old Dillenius, you are conscious of a marked difference of treatment; the old figures are more robust and graphic, and the general facies of the plant is more forcibly impressed upon the mind. But this difference is perhaps an inevitable result of our advanced knowledge of the distinctions between kindred species; the earlier artist was not haunted by the perception of minute details which make the later artist at once more timorous and exact.

The classification principally adopted by Dr. Braithwaite is that of Prof. Lindberg, by which the cleistocarpous mosses are no longer treated as a group by themselves, but are introduced into the stegocarpous families, and are regarded as imperfectly developed forms of more highly organised stegocarpous congeners. There can be no doubt that the distinctions based upon the presence or absence of a peristome and on the number of teeth in the peristome received an exaggerated amount of attention from many bryologists; they were for the moss flora somewhat as the number of stamens and pistils was in the hands of Linnæus for phænogamous plants.

Whenever a genus contains more than one species, Dr. Braithwaite gives a clavis to the species, arranged dichotomously, and this appears to us to be very carefully and well done—a fact which increases our regret that the author has not given similar guidance between the families, subfamilies, and genera of the whole group, so that the student might have been conducted by the use of the necessary differentiæ from the summum genus to the ultima species. But where so much has been given, it would be ungracious to complain that something is still wanting.

Mr. Dixon, in his preface to his "Student's Handbook of British Mosses" (1896), referred to the book now under review as "Braithwaite's splendid and elaborate work . . . which has done so much to stimulate the study of these plants in our country and which will doubtless remain our standard work for many years to come." In this generous appreciation by one botanist of the work of another, we cordially agree, and we rejoice for ourselves, as well as for the author, at the completion of a noble piece of honest work.

Before we part from the book we wish to make this review the vehicle of a thought that has frequently occurred to us

In the last number of Dr. Braithwaite's book we find a notice of *Catharinia tenella*—which has been found near Goudhurst, in Kent, by that keen bryologist Lord Justice Stirling—mixed with *Catharinia angustata.* This is only one instance of a common fact, viz. the coexistence side by side of two kindred species.

Thus, turning over at random some pages of Wilson's "Bryologia Britannica" (a book more easy to use for such a purpose than the luxurious pages of Braithwaite), we find that *Fissidens viridulus* is recorded as growing with *F. exilis, Hypnum Swartzii* as growing with *H. praelongum, Hypnum chrysophyllum* as found with *H. stellatum, Hypnum resupinatum* in like manner with *H. cupressiforme,* and *Hypnum elegans* as often growing with *H. denticulatum*; and in all these cases the two species are so nearly akin that they stand next to one another on Wilson's pages. A further search would, we feel sure, bring to light many similar cases, including those in which forms recognised only as varieties are found side by side with the normal form. This fact seems to us to be worthy of further attention. Is it due solely to the suitability of the same spot to several species of the same genus, or is it

due to some genetic relation between the two organisms, the one producing the other at various times and in divers places in the same way as the normal *Linaria vulgaris* from time to time and in this spot and the other produces the peloric form? Have we caught one species in the act of producing another? E. F.

EXPERIMENTAL MORPHOLOGY.

Einleitung in der experimentelle Morphologie der Tiere. By Dr. Hans Przibram. Pp. 142. (Leipzig and Vienna: Franz Deulicke, 1904.) Price 4 marks.

THIS volume is divided into thirteen practically independent sections, and represents the "fast unveränderte Drucklegung" of a course of lectures delivered by the author during the session of 1903–4 at the Wiener University. The author has been induced to publish these lectures by the belief that all previous works of a general nature dealing with experimental embryology have either been written wholly in support of particular theories (*e.g.* Driesch, Haacke, Herbst) or only deal with a portion of the subject (*e.g.* Davenport, Hertwig, Korschelt, Maas, Morgan, Wilson, Ziegler). The present work is intended, therefore, as an introduction to the whole subject from an impartial standpoint.

In the first section, which deals mainly with the scope of experimental morphology, the author, after weighing the various names which have been proposed for the science—Entwicklungsmechanik, Entwicklungsphysiologie, kausala Morphologie, &c. —adopts Davenport's name, "experimental morphology," but defines it as including not only the experimental study of the factors determining form in ontogeny, but also in phylogeny (Umvandlungs-physiologie), so that Driesch's term "rationelle Morphologie" would seem to be more appropriate.

The uncertainty as to the proper scope of the science which this considerable choice of names exhibits is in part due to its recent growth, but it is also due in no small measure to the close connection in which experimental morphology must always stand to the other sciences.

That the author has not been more successful than his predecessors in determining suitable limits to the subject is very clearly shown by his treatment of the section dealing with the "Specifische Bestimmung." In this section the author describes the influence of relationship in transplantation experiments, and the persistence of specific characters in the transplanted tissues. He then refers to Heape's experiment, in which normal development of an Angora rabbit is obtained, though transplanted shortly after fertilisation into the uterus of a Belgian rabbit, from which, however, the author's conclusion that transfusion of strange blood has no morphogenic influence hardly follows. Following this is an account of immunity and blood relationship experiments. If it is difficult to see why these subjects should be included in a science ostensibly dealing with the factors determining form, this difficulty is still greater when the author proceeds to consider the distribution in the animal kingdom of the various proteid substances contained in muscle fibre.

In the fourth section, "Die Bewegung-Taxis," the author gives a series of very far-fetched comparisons between the behaviour of unicellular animals and of the higher Metazoa. The sensation of thirst is compared with the hydrotaxis of the Mycetozoa, and Davenport's example is followed in regarding as rheotaxis the behaviour of fish in swimming against the stream, the only position in which they are able to breathe. Finally, the "Thigmotaxis" exhibited by an oxytrocha moving round a spherical egg, unable to leave its surface, is compared with the retreat of a cat into the corner as a dog approaches, or to the preference shown by many people for those seats in a restaurant which have their backs to the wall!

In the twelfth section, "Die Vererbung," the author, after giving a brief account of the current theories of heredity, shows how these are in "schönster Uebereinstimmung" with our recent knowledge concerning the constitution of the nucleus. This agreement is obtained by assuming reduction to consist in the elimination of whole chromosomes during the maturation divisions, the view that this process represents the belated union of the paternal and maternal chromosomes not being mentioned.

In the final section, "Die Artwandlung," the author discusses the influence of external factors in causing transmissible variations.

The wide range covered by the book, the thirteen sections of which only average ten pages each, has resulted in a somewhat superficial mode of treatment, and neither in point of comprehensiveness nor of impartial treatment can the book be said to fill the want which, according to the author, has been left unsatisfied by all previous workers. G. C. C.

ATLAS OF EMISSION SPECTRA.

Atlas of Emission Spectra of most of the Elements. By Drs. Hagenback and Konen. English translation by Dr. A. S. King. Pp. v+70 and plates. (Jena: G. Fischer; London: Wm. Wesley and Sons, 1905.) Price 27s.

THIS atlas comprises the results of an investigation of the spark, arc, and flame spectra of most of the chemical elements. Twenty-eight charts are given showing heliographic reproductions of photographs taken with the aid of two small Rowland concave gratings, each of 1 metre radius and 20,000 lines to the inch. One of the gratings had a ruled space 9 cm. broad, and was used chiefly for the region of shorter wave-length. The other had a breadth of 5 cm., and was used to photograph the less refrangible portion of the spectrum. For each group of metals two charts are given, one showing the normally visual part of the spectrum, the other the violet and ultra-violet region. The dispersion given by the gratings is such that the length of spectrum from the K line of calcium (λ 3934) to the D lines of sodium (λ 5893) is about 4·5 inches, or 11 cm., each scale division on the reproductions corresponding to

ten tenth-metres. The region of spectrum studied extends from about λ 2500 to λ 7000.

In the production of the arc spectrum, rods of the metal were used as poles whenever possible, though in many cases carbon electrodes were employed, and scraps of metal or salts of the metal volatilised on them. The selection of carbon as electrodes seems to us a very unfortunate one, as it is next to impossible to disentangle the real spectrum of a substance from the structure of the carbon bands. Surely a better method would be to use poles of some inexpensive metal the spectrum of which is a fairly simple and characteristic one, such as zinc, aluminium, or silver.

Among the spectra represented in the charts are several, such as boron, arsenic, the rare earths, the platinum group, phosphorus, selenium, which are reproduced here for the first time. The previously existing records relating to some of these were very meagre, and those now published will be distinctly useful. For some of the gaseous elements vacuum-tube spectra have been obtained.

The authors have not given—and it seems unnecessary to do so—complete lists of wave-lengths, but have confined themselves to a selection of the most characteristic lines for each element. The wave-lengths of these are given only to the nearest Angström unit or tenth-metre, which is scarcely of sufficient precision for modern spectroscopic research. A chapter of notes is given at the end of the text, touching on such points as varying numbers of lines, kinds of spectra, character of lines, division into pairs, triplets, and series, lines specially prominent in any particular light source, &c.

Notable amongst the few elements not investigated by these observers is scandium. This is unique among the rarer metals in the prominence of its lines in various celestial spectra—notably the chromosphere and stellar types of intermediate temperature—and a reproduction of its complete spectrum would therefore have been of interest.

The reproductions are generally excellent; exception must be taken, however, to that of the solar spectrum, which, apparently included as a reference spectrum, is practically useless. Upon the whole, the production of the atlas is very creditable to the authors, and without being in some ways of so elaborate a nature as Crew's or the recently published atlas of Eder and Valenta, it will, through its uniform treatment of all the elements investigated, be useful, as the authors surmise, to the physicist, chemist, and astronomer.

F. E. B.

OUR BOOK SHELF.

Précis d'Hydraulique—La Houille Blanche. By Raymond Busquet. Pp. viii+375. (Paris: J. B. Baillière et Fils, 1905.) Price 5 francs.

THIS book forms one of a series of little volumes which are being issued under the title of "Encyclopédie Industrielle," and treats of the principles of hydraulics and their applications, which possess an enhanced importance in view of the recent great extension of the employment of water-power for industrial purposes, resulting from the discovery that it can be economically transmitted to a distance when converted into an electric current. Thus, by the development of electrical transmission, it is now practicable to use waterfalls and water stored up in reservoirs, in remote mountain valleys, as sources of power for towns, of which the Falls of Niagara, supplying electrical energy to Buffalo, furnish so notable an instance; and the author has given the name of "La Houille Blanche," or white coal, to this source of power.

The subject is discussed in five chapters, dealing successively with fundamental laws, flow of liquids in pipes, flow of liquids in open channels, hydraulic motors, and creation of a fall of water; and the text is illustrated by forty-nine diagrams and drawings. The hydraulic problems relating to the utilisation of water-power are solved by aid of arithmetic and simple geometry; and the author's aim has been, by making the book neither purely descriptive nor wholly didactic, to render it serviceable to a large number of persons. In the chapter on motors, the different forms of waterwheels and the various types of turbines are described; and, finally, the principle of the hydraulic ram is explained, as being distinct from motors, and yet transforming the fall of water into useful work by raising some of the water to a considerable height. Though reservoirs have been, and are being, formed by constructing high masonry dams across narrow gorges in the valleys of mountain streams, with the object of furnishing water-power, the final chapter of this book relates exclusively to the erection of a masonry weir across rivers, with the necessary sluiceway, closed by wooden panels, for the discharge of floods, by which the ordinary water-level of the river is raised so as to enable water to be drawn off into a branch canal for supplying water-power; and it deals mainly with the requisite calculations of the flow of the river, the discharge through the sluices, the pressure on the panels, the fall available, and the section of the branch canal and of its side retaining walls. The author entertains great expectations as to the future of water-power, and considers that, whereas last century was the century of steam, the twentieth century will be called the age of water-power, or white coal.

Catalogus Mammalium, tam viventium quam fossilium. By E. L. Trouessart. Suppl. part iv., Cetacea to Monotremata. (Berlin: Friedländer and Son, 1905.) Price 8*s*.

WE have much pleasure in congratulating the author on the completion of the first quinquennial supplement, whereby an absolutely invaluable work is brought well up to date, or, rather, as nearly up to date as is possible in undertakings of this nature. We notice that in the part before us references are given in the case of well-known species to passages in which they have been recently mentioned—a plan which cannot fail to be of the greatest assistance to students.

In accordance with the recent changes in nomenclature, the titles adopted for several genera differ from those employed in the original issue, as, for instance, Orcinus in place of Orca, on account of the preoccupation of the latter term. In the case of the Edentata, the list of names proposed by Dr. Ameghino for South American Tertiary forms looms very large, and, we fear, occupies much more space than it is really entitled to claim. In this connection it may be noted that the author follows Dr. Wortman in classing the North American Eocene ganodonts as ancestral types of the true edentates, Prof. W. D. Scott's recent opposition to this view probably not having been published in time to receive

notice. The classification of the ground-sloths is much more complicated than the one adopted by older writers, the Megalotheriidæ being now split up into a number of family groups. Very noteworthy is the inclusion among the Monotremata of an extinct South American family, the Dideilotheriidæ, with four generic modifications, as if this be justified it has a most important bearing on former land connections between the southern continents. We confess, however, to a certain amount of hesitation in accepting the determination of these South American fossils until it has been confirmed by a palæontologist of unquestioned authority. In retaining provisionally the South African Tritylodon among the mammalia, Dr. Trouessart is in accord with opinions lately expressed by Dr. R. Broom. R. L.

How to Know Wild Fruits: a Guide to Plants when not in Flower by Means of Fruit and Leaf. By Maude Gridley Peterson. Pp. xliii+340; illustrated. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd.) Price 6*s*. 6*d*. net.

"YE shall know them by their fruits" might well have served as the fore-word to this little volume. It deals only "with those plants which bear attractively coloured fruits," and might, therefore, be classed by the reviewer among that very large class of books which are made to look at rather than for any more serious purpose. The very first chapter, on "Adaptations of Fruits and Seeds for Dispersal and Protection," serves to dispel that notion. It consists only of some half-dozen pages, but those pages are instructive, and, better still, suggestive. Then comes a list of "definitions," few in number, but adequate to a book of these pretensions, especially as it is supplemented by a glossary at the end. "A Guide to the Plant Families Represented" comes next in order, and consists of an analytical table by means of which the several families may be discriminated by the observation of the variations in the character of their fruits. This seems to be carefully compiled, and is, so far as we have seen, accurate, but its value can only be tested by actual use in the field.

In the second table the families and species are grouped according to the colour of their fruits. Thus the monocotyledonous families are arranged according as the colour of the fruits is red, reddish-purple, green, black, or dark-purple, or blue. Of course, this is a highly artificial mode of grouping and one subject to exception, but if these circumstances be borne in mind the table will be found useful.

Coming now to the individual plants, which are all North American, the author gives a pretty full description of each, beginning with the fruit and passing on to the foliage and flowers. These descriptions might have been materially abridged and comparison rendered easier by the omission of unnecessary particles and verbs. In this matter the example of the author's fellow-countryman, Asa Gray, might have been followed. Moreover, they are not always botanically accurate; the "fruit" of the yew, for instance, is only remotely "drupe-like," and is certainly not a "drupe," as it is said to be in the same paragraph. Conversely, the leaves of the yew are really spirally arranged, but appear to be disposed in two planes only.

It would obviously be unfair to treat this book as if it were intended as a botanical text-book, but as a help to the beginner and a means of stimulating observation it may be commended. It is well got up, remarkably free from misprints, appropriately illustrated, and provided with an index of vernacular names and one of the Latin designations of the plants described.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Kangra Earthquake of April 4, 1905.

THERE have been certain papers on Indian geological questions recently published in the *Neues Jahrbuch* and associated *Centralblatt für Mineralogie, Geol. und Pal.* (Stuttgart), in which either the data or the deductions, generally both, have been unsound. In most cases the authorship alone has been sufficient to enable us to separate those papers that are worth careful study from those that are not even worth the time necessary to read. But in the latest production one of the editors of the journal appears as a joint-author, and one wonders consequently whether the papers we have been discarding in India as untrustworthy are, after all, normal or accessory constituents of a periodical which all geologists have regarded hitherto as essential to a working library.

The paper I now refer to appeared in the *Centralblatt* No. 11 (June), entitled "Das Erdbeben im Kangra-Tal (Himalaya) von 4 April 1905," by E. Koken and F. Noetling. The authors take eight pages of text and a map to demonstrate the unusual features of scientific interest shown by the recent earthquake—the time of its occurrence, the remarkable variation in the rate of transmission of the earthquake waves in different directions, the peculiar distribution of the isoseismal lines, and the exceptional shape of the meizoseismal area. The whole of this "scientific" discussion is built on a few newspaper cuttings, in the collection of which the authors have not been sufficiently industrious to escape certain tell-tale misprints which appeared only in the newspapers of the Presidency farthest removed from the earthquake centre. One example will be sufficient to illustrate the care exercised in collecting and checking their data.

The authors on p. 336 refer to a town named Tagarmalli as only very slightly damaged, and they consequently adopt this point, which they determine to be fifty miles from the epicentre, as the maximum extension eastwards of the meizoseismal area. As a matter of fact, no such place as Tagarmalli exists, and no such name appears in any of the gazetteers of India; the most casual attempt at verification would have shown the authors that they were basing their elaborate deductions on a misprint which appeared in one newspaper only. In one of the Lahore papers the names of the two places Nagar and Manali, twelve miles distant from one another in the Kulu valley, became contracted by the printer's devil to Nagarmalli, and in this form it was telegraphed to Bombay (*Times of India*, April 14) and to Calcutta (*Englishman*, April 14); but by the accidental omission of a single Morse's dot the word reached Madras as Tagarmalli (*Madras Mail*, April 15, and telegraphic summary, April 14). Having found the clue to the authors' source of data, we find it easy to explain other equally remarkable statements in the paper. In an earlier part of their paper (p. 334) they refer to the complete destruction of the place Nagar (Naggar), without suspecting that it was one of the roots of their mythical Tagarmalli; but on this occasion they have removed the little capital town of Kulu, and, for purposes of seismological reasoning, have carried it over the snowy range into the Kangra valley. To base a series of scientific deductions on a few newspaper cuttings may satisfy the devotee of precision (*alias* accuracy) in Germany, but to neglect the simple means of verifying their facts provided by the splendid maps of the Punjab, the complete gazetteers, or even the four-penny postal guide obtainable in nearly every village, shows a carelessness that deserves the contempt of every scientific man.

But, after all, it is not the basis of data so much that is at fault, though even the purchase of a few more newspapers would have saved the authors from most of their pitfalls; it is the "scientific" superstructure that is so discreditable. When the authors noticed that the earthquake was recorded by the Bombay seismograph at

5.45 a.m., although the shock started from the focus, 1280 kilometres away, at 6.10, they examined their data with due scientific caution, and so discovered that the local time-standard of Bombay accounted for the apparently negative result; but as they obtained from their newspaper a positive record for the Calcutta seismograph, the application of the same system of scientific criticism of the time-standards did not occur to them. As a consequence, they arrive at the astonishing result that, whilst the earthquake waves travelling southwards to Bombay had a speed of 4.266 kilometres a second, those which were transmitted south-eastwards had a speed of 0.700 kilometres only.

The rest of the paper consists of "facts" and "inferences" of this kind, and whilst most are unimportant, it is desirable, perhaps, to point out that the epicentre determined by the authors is far removed from the true one. They have had to stretch their epicentre for more than forty miles to the west to account for the "complete destruction" of Pathankot. I was at Pathankot soon after the earthquake, and found it difficult to discover even a masonry crack in the town; even a few more newspaper cuttings would have shown the authors that the place was practically undamaged.

After picking a few pebbles out of this conglomerate of truth and fiction, one wonders why the paper was ever published at all. The very newspaper from which they obtained their data must have informed the authors that a thorough investigation of the earthquake had been organised by the Geological Survey. As both authors were in Madras at the time, one would imagine that a subject sufficiently interesting for a serious paper in a leading scientific journal would be worth, at any rate, a few more newspaper cuttings, even if a personal visit to the affected area were thought to be, for private reasons, inconvenient. We take it for granted that the long experience of both authors must have brought them into contact with the etiquette observed by scientific men, and that neither would consciously risk the recognised danger of forestalling the results of a thorough investigation by the publication of conclusions obtained from unverified data. But whatever the object, if the editor of a leading scientific journal can join in the production of such a paper, the future of scientific literature in Germany may yet give us entertainments as surprising as any of the recent efforts of the Russian Navy.

Of the Kangra earthquake, as well as of the other Indian questions which have been treated recently in the *Centralblatt* with an equal regard for accuracy, those who wish to know the truth will be provided with details in due season. Within a few days after the disaster occurred, every telegraph operator, meteorological observer, and district official north of the latitude of Bombay was provided with a complete guide for reporting the resulting phenomena, and the reports so obtained have since been supplemented by a detailed examination of the affected area by five officers of the Geological Survey. The observations made will be summarised first in the next part of the records, and the full details will form a special memoir, now in course of preparation. When these reports are ready, it will be seen that the actual facts, though in ways interesting and novel, are scarcely so strange as German fiction.

Calcutta, July 20.

The Transverse Momentum of an Electron.

WHEN Newton's third law is applied to an electron, it makes

$$\mathbf{F} = \dot{\mathbf{M}} + \dot{\mathbf{N}}, \qquad (1)$$

where $\mathbf{M}$ is the "momentum" in the field, or that part of the time integral of the force on the ether which is in the field, or $\Sigma\, \mathrm{V}\mathbf{DB}$, and $\mathbf{N}$ is the momentum already wasted, whilst $\mathbf{F}$ is the applied force on the electron. Similarly, Newton's fourth law (or the Scholium to the third) makes

$$\mathbf{Fu} = \dot{\mathrm{U}} + \dot{\mathrm{T}} + \mathrm{W}, \qquad (2)$$

if $\mathbf{u}$ is the velocity of the electron, U the electric and T the magnetic field energy, and W the rate of waste of energy.

Now, both W and $\dot{\mathbf{N}}$ are known in terms of the velocity and acceleration of the charge at any moment by formulæ I gave in NATURE, October 30, November 6, 1902. But when applied to (1), (2), these equations do not let us determine $\mathbf{M}$ generally in terms of the velocity and acceleration, on account of the variability of the state of the field, and the waste of energy and momentum. $\mathbf{M}$ is indefinite. But in long-continued forced circular motion of a charge, $\dot{\mathrm{U}} + \dot{\mathrm{T}} = 0$. So

$$\mathbf{Fu} = \mathrm{W} = \mu \mathrm{Q}^2 a^2 / 6\pi v \kappa \qquad (3)$$

(*loc. cit.*), where Q is the charge, and a the acceleration (or u^2/R, if R is the radius of the orbit). Also, $\kappa^2 = 1 - u^2/v^2$. The direct or $\mathbf{u}$ component of $\mathbf{F}$ is therefore known. We also have (*loc. cit.*)

$$\dot{\mathbf{N}} = (\mathbf{u}/v^2)\mathrm{W}. \qquad (4)$$

Using this in (1), along with (3), we come to

$$\kappa^2 \mathbf{F}_1 = \dot{\mathbf{M}}_1, \qquad \mathbf{F}_2 = \dot{\mathbf{M}}_2, \qquad (5)$$

where $\mathbf{F}_1$ is the $\mathbf{u}$ component, and $\mathbf{F}_2$ the transverse component, towards the centre.

Thus only the part $\kappa^2 \mathbf{F}_1$ of the direct force is associated with the transverse or centripetal force $\mathbf{F}_2$ in keeping up the revolving state, the rest of $\mathbf{F}_1$, that is, $(u^2/v^2)\mathbf{F}_1$, being the wasted part as regards momentum, although the whole of $\mathbf{F}_1$ is concerned in the waste of energy.

Now, $\dot{\mathbf{M}} = \mathrm{V}\mathbf{nM}$, if $\mathbf{n}$ is the angular velocity. That is,

$$\dot{\mathbf{M}} = \dot{\mathrm{M}}_1 \mathbf{u}_1 + \mathrm{M}_1 \dot{\mathbf{u}}_1 + \dot{\mathrm{M}}_2 \mathbf{a}_1 + \mathrm{M}_2 \dot{\mathbf{a}}_2, \qquad (6)$$

if $\mathbf{u}_1$ and $\mathbf{a}_1$ are unit vectors, making

$$\dot{\mathbf{u}}_1 = (u/\mathrm{R})\mathbf{a}_1, \qquad \dot{\mathbf{a}}_1 = -(u/\mathrm{R})\mathbf{u}_1. \qquad (7)$$

Also $\dot{\mathrm{M}}_1 = 0$, $\dot{\mathrm{M}}_2 = 0$, because the motion is steady. So we convert (5) to

$$\kappa^2 \mathbf{F}_1 = \dot{\mathbf{M}}_1 = -\mathrm{M}_2 (u/\mathrm{R}) \mathbf{u}_1, \quad \mathbf{F}_2 = \dot{\mathbf{M}}_2 = \mathrm{M}_1 (u/\mathrm{R}) \mathbf{a}_1. \quad (8)$$

Finally, although we get no formula for M_1, we do obtain a complete formula for M_2, viz.,

$$\mathrm{M}_2 = -\ \mu \mathrm{Q}^2 a / 6\pi v \kappa^2. \qquad (9)$$

This is the transverse momentum of Q in steady circular motion, without any limitations upon the size of the velocity and acceleration, save the usual ones, $u < v$, and a not excessively great in regard to the diameter of the electron.

It would seem that an integration over the whole field, in which $\mathbf{E}$ and $\mathbf{H}$ are known (*loc. cit.*), is required to find $\mathbf{M}_1$, the direct momentum. If, however, the acceleration is infinitesimal, the known formula for M_1 in steady rectilinear motion may be employed, viz. $\frac{1}{2}\mathrm{M}_1 u = \mathrm{T}$.

Finally, I have pleasure in saying that Mr. G. F. C. Searle, F.R.S., led me to see that my waste formulæ led to the formula (9) for the transverse momentum, by submitting to me a calculation of M_2 in the special case of infinitesimal acceleration and velocity. He made no use of the waste formula, not being aware of it, but, since in the circumstances the waste is infinitesimal, it did not matter. In fact, $\frac{1}{2}\mathrm{M}_1 u = \mathrm{T}$ leads to the reduced special value of the transverse momentum when u and a are infinitesimal. The argument became somewhat obscure by the want of comprehensiveness, but the result agrees with (9).

OLIVER HEAVISIDE.

August 20.

A Parasite of the House-fly.

I SHOULD be very glad if Mr. Hill (p. 397) would send me a few specimens of the *Pseudoscorpiones* he has found attached to common house-flies, and I will endeavour to identify them for him. There are several genera of this order represented in the British fauna, and it is probable that all the species occasionally attach themselves to the legs or wings of larger insects and arachnids. There is some doubt, however, whether this is a case of true parasitism. It may be that the occasional association of these small arachnids with larger and more rapid arthropods is of importance to the species in providing a means for a wider geographical distribution.

SYDNEY J. HICKSON.

The University, Manchester, August 25.

THE TRANSPLANTATION OF SHELLFISH.

FOR the past three years an interesting series of experiments has been carried out on the Lancashire coast by the officials of the Lancashire and Western Sea Fisheries Joint Committee with the object of improving the condition of the public shell fisheries. It has for some time been felt that the introduction of restrictive legislation has not removed all the difficulties incident to the successful protection of cockle and mussel beds where the beds do not form part of a several fishery, that is to say, are under private ownership. Restrictive methods such as the abolition of destructive implements of fishing and the prevention of the removal of cockles and mussels under a certain size, no doubt do protect beds from excessive depletion, but there are various factors which require other treatment for their solution. In some districts, notably at Morecambe, beds have become overcrowded, so that thinning is an absolute necessity. In one instance the present writer counted 116 small mussels adhering to an area of one square inch. In other cases there is the danger that the molluscs may become smothered by sand, or that the "spat" has struck too near the high-water mark for the mussels to develop to the size at which they may legally be taken by the fishermen. Three years ago the scientific sub-committee of the Lancashire Sea Fisheries District expended a small sum of money in order to try the experiment of thinning the Morecambe mussel beds. The shellfish that were removed were transplanted to other suitable areas nearly or entirely bare of shellfish.

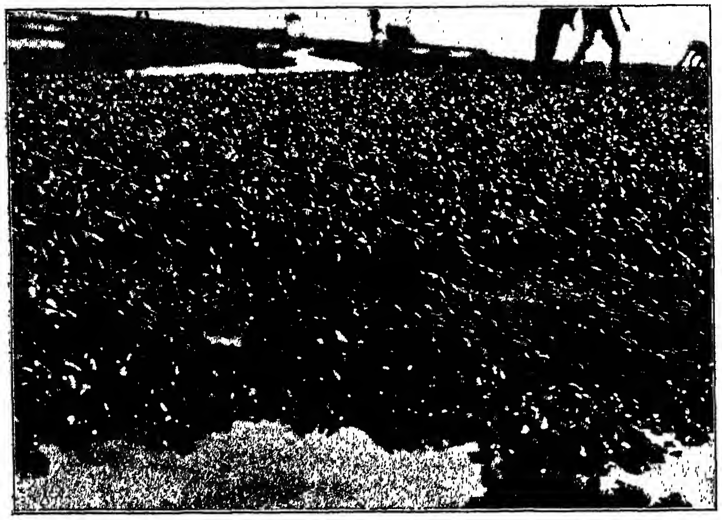

FIG. 1.—An overcrowded Morecambe mussel bed.

Samples of the mussels were taken before and at frequent intervals after transplantation. It was found that the experiment was successful, and in the following year (1904) the work was extended to other districts on the Lancashire coast, and attention was not only directed to mussels, but cockles were transplanted from overcrowded beds in the neighbourhood of Southport. This year the experiment has been proceeded with still further. Cockles have been transplanted successfully at Lytham and Southport, and mussels at Morecambe, Flookburgh, and in the Wyre and Lune estuaries. The work is carried out under the superintendence of the committee's bailiffs, and the shellfish gatherers are paid per tide for the work involved as well as for hire of boats. The mussels are generally removed at the commencement of the close season—which lasts in this district from April to August inclusive—so that the fish have a chance of accommodating themselves to their new environment without disturbance. Care is also taken to remove shellfish under the legal size so that their growth can be tested before they become "sizeable" fish for the market. The renewed growth which takes place in old cockles and mussels which had previous to removal not grown for years is remarkable.

The amount of shellfish transplanted is in the aggregate considerable, as may be seen from the following. In four days at Morecambe alone 152 tons 11 cwt. of mussels were re-deposited in localities favourable for their vigorous growth. At Lytham undersized cockles were removed from places where they were left dry too long by the receding tide, as a consequence of which their growth was checked, to more suitable ground where their growth was likely to be facilitated. This work is rendered possible by the Sea Fisheries (Shell Fish) Regulation Act of 1894, which *inter alia* provides that a local fisheries committee shall have power to stock or re-stock any public fishery for shellfish, and for that purpose to incur such expenses as may be sanctioned by the Board of Agriculture and Fisheries. The fishermen themselves, who may invariably be trusted to express their criticism of any work undertaken by the committee in a frank and outspoken manner, in this case express their appreciation of the efforts of the committee to improve and maintain the shellfish industry on the Lancashire coast. The value of the cockle industry to the Lancashire cocklers is approximately 20,000*l.* per annum.

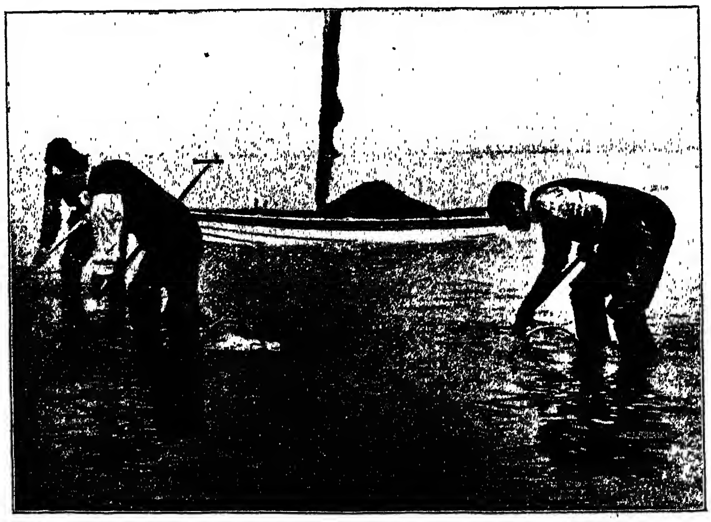

FIG. 2.—At work with the "Craam."

THE STANDARDISATION OF SCREWS.

THE question of standardising screw threads and limit gauges has long received the careful attention of engineers, and in Great Britain considerable advantage has accrued from the publication of an interim report (No. 20, April, 1905) of the Engineering Standards Committee, dealing with the form and pitches of screw-threads most suitable for general engineering purposes. Having regard to the fact that the Whitworth thread is in general use throughout the country, the committee does not recommend any departure from this form of thread. The existing Whitworth series of pitches for screws from ¼ inch to 6 inches in diameter does not, however, satisfy all requirements, and the committee has drawn up tables of standard sizes which will doubtless meet with general adoption. For all sizes of screw threads below ¼ inch in diameter the committee recommends the adoption of the pitches, sizes, and form of thread proposed by the British Association Small Screw Gauge Committee in 1884.

In France an influential committee of the Société d'Encouragement pour l'Industrie nationale, consisting of General Sebert and Messrs. Carpentier, Sauvage, Masson, Sartiaux, and Zetter, has devoted attention to the subject, and has published in the current issue of the Bulletin of the society a scheme for extending the international system to screws of less than 6 millimetres in diameter. The committee recommends the adoption, between the diameters of 1 millimetre and 5.5 millimetres inclusive, of twelve screws as shown in the following table:—

Diameter mm.	Pitch mm.	Diameter mm.	Pitch mm.
1·0, 1·25	0·25	3·0, 3·5	0·60
1·5, 1·75	0·35	4·0, 4·5	0·75
2·0, 2·5	0·45	5·0, 5·5	0·90

The six largest screws of this series are those first proposed by the second committee of the Chambre syndicale des Industries électriques. The screws of 2 millimetres and of 2.5 millimetres for which the pitch is 0.5 millimetre having proved too coarse, have received the pitch of 0.45 millimetre. The 1 millimetre screw has received the pitch of 0.25 millimetre in order to bring the new series into accord with the Thury series, which is used for very small screws. The scheme appears likely to be favourably received by the Swiss and German industries.

The initial accuracy of a helical surface, as distinct from the sectional form of the thread, is dependent upon the accuracy of the leading screw of the machine upon which it is cut, and thus the leading screw becomes a generating master-gauge which instead of being used solely for gauging is called upon to do work involving wear. The importance of maintaining the accuracy of these leading screws in connection with the production of the interchangeable parts of modern guns and gun mountings led to the appointment in November, 1900, of a committee consisting of Mr. H. F. Donaldson, chief superintendent of the Royal Ordnance Factories, president, Mr. R. Matthews, Lieutenant A. T. Dawson, R.N., Mr. H. J. Chaney, Dr. R. T. Glazebrook, F.R.S., and Colonel H. C. L. Holden, R.A., F.R.S., to consider the provision of standard leading screws for screw-cutting lathes, and its report to the secretary of the Army Council has just been published. The committee finds that the only practical way to obviate the difficulty found in securing absolute interchangeability, even on short lengths of large screws, is to provide centrally special machinery for the supply of large screws of certified accuracy. Approval of funds for this purpose was accordingly sought and obtained. The machine, which was made by Messrs. Armstrong, Whitworth and Co., of Manchester, was designed to secure accuracy over 3 feet length of screw. Measurements made after the machine was installed in the special chamber erected for it at the National Physical Laboratory showed that the movement of the tool carriage did not vary from that produced by a true screw of the same reputed length by more than 0.0002 inch in its full length, and after insertion of a correcting cam by more than 0.0001 inch at any one point, and that corrected microscopic scale readings and independent end-measure readings did not differ by more than 0.0001 inch at any point. The committee recommends that all accurate screws required for Government engineering work be supplied in future from screws originated from or corrected by the standard leading-screw adjusting machine at the National Physical Laboratory, and that facilities be given to private firms to correct heavy screws of ½-inch pitch by this machine. The house in which the machine is installed at the National Physical Laboratory presents many points of interest, as the greatest possible precautions have been taken to maintain uniformity of temperature and freedom from vibration.

THE STERILISATION OF WATER IN THE FIELD.

IT is well known that disease is more fatal to the soldier in a campaign than the bullets of the enemy. Thus in the South African campaign the total deaths from disease were almost exactly double those due to wounds in battle. The diseases which persistently dog the track of an army are typhoid or enteric fever, dysentery, and, in certain countries, cholera, and to these the principal mortality is due.

As regards their incidence, much necessarily depends on the climatic and physical conditions of the country in which the war is being carried on. Both in the Spanish-American war and in the South African war typhoid fever proved a terrible scourge.

These diseases are usually largely water-borne, but it must be recognised are not exclusively so, and, therefore, attention to the water supply alone will not wholly prevent them. In the Spanish-American war, for instance, the commission which investigated the typhoid fever epidemics of the United States Army reported that infected water was not an important factor in its spread. The other agents concerned in the dissemination of this disease are dust and flies, blowing or carrying infection from infected latrines, and gastro-intestinal disturbance, the result of heat, fatigue, and bad food rendering the troops more vulnerable. It cannot be doubted, however, that a pure water supply would do much to lessen the incidence of typhoid fever and dysentery, and probably quite prevent cholera.

A pure water supply can partially be secured by three methods; (1) by a careful selection of the camping grounds and protection of the water supply from pollution; (2) by deep-driven artesian wells; and (3) by the sterilisation of the water; or a combination of these methods may in many instances be adopted. But whatever method is applied it must be remembered that soldiers parched with thirst *will* drink any water that comes in their way. As regards the first method, the selection of the camping grounds, &c., it is reported that it has been adopted with considerable success by the Japanese in the present campaign; a corps of medical officers is sent on ahead to select the camping ground and survey the water supply;

sources which seem to be polluted can thus be largely excluded, and by judicious arrangement of the latrines and by posting guards to prevent individual pollution and the drinking of suspicious supplies much may be done to ensure pure water for drinking. As regards artesian wells, surface wells and streams are the main source of danger, but by driving deep artesian wells a pure water is obtained. This, however, would be possible only under special conditions in certain districts and for comparatively small contingents.

There remains the method of sterilisation, which, if it could be universally applied, would necessarily prevent water-borne disease.

The three methods applicable for the sterilisation of water are :—(1) filtration through a porous porcelain filter such as the Pasteur-Chamberland; (2) heat; and (3) chemical germicides.

Filtration through a porcelain filter, if it can be applied, would be efficient, but it necessitates a good deal of apparatus, and the filter candles are fragile. It is a good method under efficient supervision, but is more applicable for small contingents than a large army.

Heat has been adopted by many inventors, and Mr. Arnold-Forster, M.P., recently inspected a number of devices based on this principle. In most, *e.g.* the Lawrence, Forbes, Mallock, and Tuckfield and Garland machines, the water is heated to the boiling point, but in the Griffiths machine it is assumed (from experimental evidence) that heating to about 170° F. suffices, which results in a considerable economy in fuel. In all the machines the out-going hot water warms the in-going cold water, and is itself cooled thereby. Important considerations are weight and fuel, and these have received much attention from the respective inventors.

The Mallock machine, which, including pump and cases, weighed 153 lb., with a consumption of one pint of kerosine gave 50 gallons of water an hour at a temperature of 88° or 90°, the temperature of the in-going water being 74°. The Tuckfield and Garland machine, of which the steriliser weighed 198 lb. and the heating apparatus 126½ lb., gave 40 to 50 gallons at a temperature of between 104° and 110°, the temperature of the in-going water being 78°; its inventors state that it requires 20 lb. or 30 lb. of kerosine for 1000 gallons of water, and in it the water to be sterilised is heated by steam generated in a separate boiler. The Griffiths machine, weighing 120 lb. and using 1½ pint of kerosine an hour, yielded 26½ gallons of water an hour at a temperature of 92°, 45 gallons an hour at a temperature of 103° to 106°, and 72 gallons an hour at a temperature of 105°, the temperature of the supply being in all cases 67°. The Lawrence apparatus, weighing, with water-tank and case, 168 lb., and working with supply water at 74°, had a temperature of delivery of 88° to 90°, but it used two pints of kerosine an hour and the quantity of water delivered was only 30 gallons an hour. Finally, the Forbes machine, weighing 130 lb., delivered 15 gallons of water an hour, with an oil consumption of one pint, the temperature of supply being 74°, and of delivery from 86° to 90°.

Lastly, there remain the chemical germicides. Obviously these must have no deleterious action on man in the quantities employed; they should not be corrosive to metal vessels, they should be portable and act rapidly. Alum has long been employed for purifying water, but its action is to *clarify* a turbid water, and it cannot be relied on to *sterilise*. Potassium permanganate may be used, but is not very efficient or trustworthy, and both it and alum necessitate the water being left for some hours. Some three or four years ago Parkes and Rideal introduced bisulphate of soda for the purpose. It may be put up in tablets, and in quantities of 15 grains to the pint or thereabouts destroys the typhoid bacillus in water within half an hour, imparts little or no taste to the water, and is quite harmless. Lastly, there is the method introduced lately by Lieut. Nesfield, I.M.S., in which chlorine is the sterilising agent, and this, after acting, is "killed" by the addition of sulphite of soda. For small quantities of water, iodine may be similarly used. This last method was recently described in NATURE (July 27, p. 307), and has much to commend it.

R. T. HEWLETT.

PROF. JULES OPPERT.

On August 21 died Prof. Jules Oppert, the last of the band of great scholars who were the pioneers of cuneiform decipherment. His name will go down to posterity with those of Rawlinson, Hincks, de Saulcy, and Fox Talbot, with whom he helped to lay the foundations of the flourishing science of Assyriology. Like them, too, he has now laid down the pen for ever.

Born of Jewish parents in Hamburg on July 9, 1825, Jules Oppert began the study of Sanskrit and Arabic under Lassen and Freytag at Bonn, afterwards devoting himself to Zend and Old Persian at Berlin and Kiel. In 1847 he published his first work, entiled "Das Lautsystem des Altpersischen," in which he discovered that *m* and *n* had to be supplied before a following consonant in Old Persian, and thereby supplementing the alphabet. At that time the German law did not permit Jews to hold professorial posts, so in the same year he moved to France, where he was appointed professor of German at Laval, and afterwards, in 1850, at Rheims. The favourable reception accorded to his work on the Achæmenian inscriptions obtained for him, in 1851, a post on the staff of the scientific mission dispatched to Mesopotamia by the French Government, under MM. Fresnel and Thomas.

On his return in 1854, Oppert devoted himself entirely to the study of Assyrian and Babylonian, and between 1857 and 1863 the several volumes of his great work "Expédition scientifique en Mésopotamie" saw the light. While the linguistic value of this has always been of the greatest importance, the topography is less fortunate, the late author having been led into the mistake that the ruins of ancient Babylon were much larger than they really are. In 1855 he visited the British Museum and the museums of Germany to report on the progress made in cuneiform studies, and on his return in the following year he was decorated with the Cross of the Legion of Honour, and obtained the post of professor of Sanskrit and comparative philology at the school of languages attached to the Imperial Library at Paris. Two years previously he had become a naturalised Frenchman. In 1859 he published a Sanskrit grammar, closely followed by "Éléments de la Grammaire assyrienne." In 1865 there appeared from his pen a short history of Babylonia and Assyria. In 1881 he succeeded the late M. Mariette as a member of the Institute of France, being elected president of the same society ten years later—perhaps the highest honour a French *savant* can receive.

The versatility of the late Prof. Oppert was extraordinary. His papers, published in various scientific journals, cover an astonishing range of subjects. Not the least interesting are his contributions to astronomical chronology, in which subject he took a deep interest. In "La Chronologie biblique fixée par les Éclipses des Inscriptions cunéiforme" (*Rev. Archeol.*, 1868) he attempted to reconcile the dates

of the Old Testament with those of the Assyrian monuments. Other astronomical works are:—"Die astronomischen Angaben der assyrischen Keilinschriften" (Band xci., *Kais. Akad. der Wissensch.*, 1885), "Un Annuaire astronomique babylonien utilisé par Ptolémée (*Journ. As.*, 1890), "Les Éclipses mentionnées dans les Textes cunéiformes" (*Zeitschr. für Assyr.*, 1897), and many others of less importance. One of his last works was a contribution to chronology, entiled "L'Année de Meton" (*Rev. des Études grecques*, 1903). In his early days he had been a great champion of the genuineness of cuneiform decipherment, when its opponents counted among their ranks such great men as Renan and many others. He was one of the historic four who, at the invitation of the sceptics, produced a translation of the cylinder of Tiglath-Pileser I., which was read at a meeting of the Royal Asiatic Society by the president, and found to be substantially the same as the translations of Rawlinson, Hincks, and Fox Talbot, all of whom had bound themselves over not to collaborate or communicate with one another.

NOTES.

AT the time of going to press, no message had been received from Sir Norman Lockyer as to the eclipse observations at Palma. The following telegram from the Astronomer Royal had, however, reached the Royal Society:—"Eclipse satisfactorily observed, but partially cloudy. Photographs with all instruments."

PROF. RONALD ROSS informs us that the announcement to the effect that he has proceeded to New Orleans with Prof. Rubert Boyce, in connection with the outbreak of yellow fever there, is without foundation.

THE sixteenth annual general meeting of the Institution of Mining Engineers will be held at Manchester on September 13–16. The following papers will be read, or taken as read:—Leading features of the Lancashire coalfield extended: J. Dickinson; up-to-date electrical power distribution: R. L. Gamlen; can explosions in coal-mines, with their associated toxic fatalities, be prevented? B. H. Thwaite; earth in collieries, with special reference to the recently issued departmental rules: S. F. Walker; the value of mollusca in Coal-measure stratigraphy: J. T. Stobbs.

THE Local Government Board has issued a circular to borough councils and other local authorities respecting cerebro-spinal or "spotted" fever. This disease has recently been somewhat prevalent in Central Europe and in America, but the Board expresses the opinion that there has been no increase of the disease in England. For the guidance of local authorities the chief features of the disease are detailed, and, should an outbreak occur, the Board is prepared to advise the authority respecting it and to sanction notification.

DURING the past week the weather over the British Islands has been very unsettled; on Thursday last, heavy rain set in over many parts of Ireland, and continued almost without interruption for about thirty-four hours. The amounts measured during this period were 4·17 inches at Greystones, 4·33 inches at Dublin, 4·71 inches at Dundrum, and 5·09 inches at Bray, causing disastrous floods in various parts of that country. At Little Bray, the inmates of the lower-lying houses had to be rescued by boats. Sharp thunderstorms occurred in London and other parts on Sunday, Monday, and Tuesday, causing much damage to property. At Leigh, in the neighbourhood of Tonbridge, the trunk of an oak tree was torn in half, and a man who was seeking shelter under it was killed. During this period, rainfall has been considerable in all parts of the British Islands; in the twenty-four hours ending at 8h. a.m. on Tuesday, August 29, the amounts at Oxford and Yarmouth exceeded an inch, and an inch and a half was measured in the neighbourhood of London.

THE programme of the Iron and Steel Institute for the meeting to be held at Sheffield on September 26–29 includes the following list of papers:—Wear of steel rails on bridges: T. Andrews, F.R.S.; metallurgical department of Sheffield University: Prof. J. O. Arnold; thermal transformation of carbon steels: Prof. J. O. Arnold and A. McWilliam; nature of troostite: Dr. Carl Benedicks; occurrence of copper, cobalt, and nickel in American pig-irons: Prof. E. D. Campbell; transformations of nickel steels: L. Dumas; on steel for motor-car construction, and on vanadium steels: L. Guillet; presence of greenish-coloured markings in the fractured surface of test pieces: Captain H. G. Howorth; over-heated steel: A. W. Richards and J. E. Stead, F.R.S.; segregation in steel ingots: B. Talbot; manipulator for steel bars: D. Upton; influence of carbon on nickel and iron: G. B. Waterhouse.

ATTENTION is directed by the *Engineering and Mining Journal* of New York to a new development in mining which has not been generally noticed, namely, the working of alluvial tin deposits by dredging in the same manner as that followed in the case of gold-bearing gravel. In New South Wales the dredging for tin ore has become an established practice. In 1904 there were seven dredges in operation, which obtained 319 tons of tin ore, valued at 26,000*l*. The successful development of this practice in New South Wales suggests that it might possibly be applied with advantage in the Straits Settlements and elsewhere.

IN a paper read before the Geological Society of America, Mr. George P. Merrill described a large block of massive serpentine traversed by veins of so-called asbestos from Thetford, Canada, now exhibited at the United States National Museum at Washington. Incidentally discussing the origin of the veins, he suggested that the vein cavities are shrinkage cracks filled by a process of crystallisation extending inward from either wall, and compared the veins to the shrinkage cracks formed in septarian nodules of clay ironstone, and their filling with fibrous material to the crystallisation of fibrous gypsum in limestone.

AN ordinance relating to lead works has just been issued by the German Imperial Chancellor. The employment of women and lads in dust chambers and flues and in the transport of the dust is prohibited. The workmen employed at the furnaces may not work more than eight hours a day. The same rule applies to the workmen working inside cold furnaces or engaged in cleaning dust chambers and flues containing wet dust. Workmen engaged in cleaning dust chambers and flues containing dry dust are not permitted to work more than four hours a day inside such chambers and flues, and not more than eight hours a day in all. Food must not be taken to the working places. Working-suits, respirators, and gloves must be worn. Smoking cigars and cigarettes during work is forbidden. The rules will come into force on January 1, 1906.

THE most important paper in the June issue of the *Proceedings of the Philadelphia Academy* is perhaps one

by Mr. J. A. G. Rehn on the brown grasshoppers (Acridiidæ) of Costa Rica, in the course of which a number of new species are described. The collections examined included nearly three hundred specimens.

It may be remembered that the remains of James Smithson, the founder of the Smithsonian Institution, who died in 1829 and was buried in the English cemetery on the heights of San Benigno, Italy, were removed to Washington last year and formally handed over to the Regents of the institution. The body, upon its arrival in Washington in January, 1904, was placed temporarily in a room in the Smithsonian building containing the relics of Smithson. While resting there, the remains were examined by medical experts and found to be in a remarkable state of preservation. Meanwhile a small mortuary chapel was prepared for them on the immediate left of the north entrance of the Smithsonian building, and on March 6, 1905, the remains were brought to this chapel and, in the presence of the Regents, replaced in the original tomb,

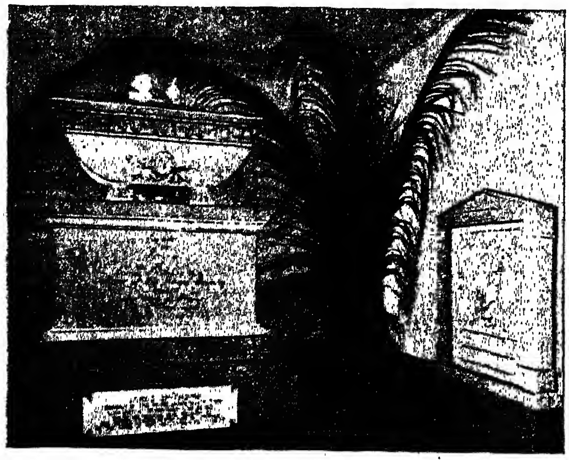

FIG. 1.—Interior of Smithson Mortuary Chapel, Smithsonian Institution.

shown in the illustration, which has been reproduced from the *Smithsonian Quarterly* (vol. xlviii.), where they will rest until Congress makes adequate provision for their fitting interment.

IN *La Nature* of July 29 Prof. E. T. Hamy, the well known professor of anthropology at Paris, gives an account, illustrated by reproductions from photographs of the animal shortly after death, of a gigantic gorilla recently shot on the Sangha River, Congoland. It is said to have measured no less than 2 metres 30 cm. (7 feet 6¾ inches), and the height of the carcase in a sitting posture reached, as shown in the photograph, to the waist of a full-grown native. Prof. Hamy believes the specimen to indicate a new race, if not a new species, of gorilla.

FROM the report on the museums of the Brooklyn Institute of Arts and Sciences for 1904 we learn that special attention is being devoted to improving the installation of the children's museum. As first arranged, this part of the exhibition series was found to overlap in a considerable degree the ordinary collection, and steps were accordingly taken to do away with this duplication. Elimination, both from the museum and the illustrative lectures, of material not likely to interest children has also been undertaken, with the result that the collection has been entirely re-modelled, and is now as suitable for its present purpose as it can be made.

THE chief feature of the July issue of the *Emu* is formed by the plates, one of which gives a full-sized figure, from a photograph, of the New Calendonian kagu (*Rhinochaetus jubatus*), to which allusion has been made previously in these columns; while others (also from photographs) are devoted to the illustration of the parasitic habits of Australian cuckoos, which appear to be very similar to those of our own species. Of these three plates, one represents a young bronze-cuckoo (Chalcococcyx) ousting a blue wren (Malurus) from its rightful nest, the second a young fan-tailed cuckoo (Cacomantis) in a brown tit's (Acanthiza) nest, while the third shows a young bronze-cuckoo in the nest of a brown tit.

IN the *Zoologist* for August the editor commences a series of articles on the factors conducive to extermination of species, dealing in this instance with natural as distinguished from human agencies. Unfortunately the article is marred by several serious mistakes. We are told, for instance, that "the opossum" is the only non-Australian mammal, the cuscuses of Celebes and Cœnolestes of Brazil being ignored; while in the same sentence we are informed that monotremes are confined to New Zealand! Again, we are unaware what ground there is for the statement that fossil marsupials are known from Asia. Minor errors, such as nummulitids for nummulites, are also noticeable. In the same issue is a very interesting article by Mr. H. H. Patterson on the heronry at Reedham, Norfolk. In the case of a note on the occurrence of the lesser horse-shoe bat in Shropshire, the editor might have pointed out that Noctilio is not the generic title for these bats.

THE fourth volume of "The Museums Journal" (Dulau and Co.), edited by Mr. E. Howarth, covers the period from July 1, 1904, until June 30 of the present year, and contains the report of the council submitted at the Norwich Conference of 1904. Although now somewhat ancient history, that report records continued progress on the part of the association, both as regards membership and funds for permanent investment. It is also satisfactory to learn that the journal itself is becoming more and more widely appreciated, and consequently shows a constant tendency to increase in bulk. The museums directory, or list of the museums in the United Kingdom, is likewise proving larger than was anticipated, the volume just received continuing the list from London to Stalybridge inclusive, together with supplements. One of the difficulties which the editors experience is in getting local curators to send in the names and objects of the institutions under their charge. The attendance of delegates from foreign museums at the last two conferences is another satisfactory feature in connection with the progress of the association. Among features connected with progress in regard to museum work, attention may be directed to the adoption by the Museum of the Federated Malay States of the card-system for the registration of specimens.

MUCH interesting information with regard to animals in menageries and the evolution of museums on the other side of the Atlantic is conveyed in a pleasant style in the course of an illustrated article by Mr. E. S. Hallock published in the August number of the *Century Illustrated Monthly Magazine*. "The menagerie," writes the author, "developed along with the circus, but differed from the latter in being an animal-show pure and simple. . . . Some menageries were stationary, while others travelled from place to place in large vans." The "dime-

exhibition" and the "curiosity-house" were devoted more to the exhibition of rare and interesting animals, monstrosities, &c., and from these, by the elimination of the "freak" element, are derived the modern American scientific museums. Reference is made to the camel exhibited in London in 1650, the Indian rhinoceros (described by Dr. Parsons) in 1685, and to Wombwell's unrecognised gorilla. Less well known is the case of the first great ant-eater exhibited in the London "Zoo," which was purchased about 1850 from two sailors, by whom it had been brought from Rio, for 300*l.*; and also that of a full-grown mandrill captured on board a slaver, and exhibited in Bristol in 1828, and later on in London. The most interesting record in the article is, however, the reference to a pair of South African giraffes imported into America in 1836, the same year in which the London gardens received their first representatives (of the northern race) of the species. In stating that the London establishment received its first representative of the southern form in 1895 the author makes a pardonable error, the fact being that the true southern race never has, so far as we know, been exhibited alive in this country.

THE most generally interesting feature in the report of the Indian Museum, Calcutta, for 1903–4 is the reference to a suggestion made by the director of the natural history branch of the British Museum that all the Indian type specimens might be transferred to the institution under his charge. The suggestion—which Major Alcock refers to in his section of the report as "most reasonable"—was largely based on the fact that the climate of Calcutta renders "types" as objects of reference almost useless, and that the interests of science would accordingly be advanced by their transference to the chief natural history centre of the British Empire. By the terms of their trust the trustees found themselves, however, unable to hand over the "types" formerly belonging to the Asiatic Society of Bengal, while they were disinclined to accede to the request as regards other "types" for fear of handicapping workers in India. Commenting upon this decision and its consequences, Major Alcock directs the attention of the Government of India to the administration of the museum, stating that the zoological staff is altogether inadequate. "An imperial museum of natural history," he writes, "such as the zoological section of the Indian Museum was designed to be, should be at once a complete and modern index of the fauna of the country, an object lesson in the more important general principles of zoology, an unfailing magazine of well-preserved material for research and distribution, and a centre where natural science is advanced by the discovery and publication of new facts. The facts that the Museum receives a grant for teaching-preparations from the local Government, and has decided that its 'types' must be kept on the spot for reference, indicate that this is the standard the Trustees wish realised. But grants of money and the possession of historic 'types' are not enough; equally essential are well-qualified paid assistants and reliable machinery for collecting new material and replenishing old."

A VERY interesting paper is contributed on the magic origin of Moorish designs to the *Journal of the Anthropological Institute* (July–December, 1904) by Dr. Westermarck. The magic consists entirely in the methods employed to ward off the evil eye, the fear of which is so potent in countries bordering the Mediterranean. The designs consist of hands, crosses, eyes, rosettes, squares, octagons, triangles, and innumerable conventional embroidery patterns; but they are all grouped round one central idea, the intention being to throw back the evil influence emanating from the eye, by some counter-charm. This is usually done by stretching out the five fingers of the right hand, and Dr. Westermarck shows how all these various designs can be traced to some elaboration of fives, originally representing the five fingers, or of eyes, for if baneful energy can be transferred by the eye, it can obviously also be thrown back by the eye. Sixty-two illustrations of these counter-charms accompany the article.

IN the course of a note on the supply of water to leaves on a dead branch, printed as part ii. of vol. xi. of the *Scientific Proceedings of the Royal Dublin Society*, Prof. H. H. Dixon adduces evidence, based on experiment, to show that when a portion of a stem is killed by heat, the cells give off poisonous or plasmolysing substances; for some such reason it appears that leaves attached to a dead branch wither much more rapidly than leaves on a living twig. In the first part of the same volume Mr. J. Adams discusses the effect of very low temperatures on moist seeds.

MR. D. HOOPER has a historical and explanatory note on the ancient eastern medicine known as lycium or rusot in the *Journal of the Asiatic Society of Bengal* (vol. lxxiii., part ii., No. 4). The identity of rusot with the Indian lycium of the ancients was first pointed out by Dr. J. F. Royle, who found out that it is an inspissated extract prepared from the wood and roots of several species of Berberis. Mr. Hooper's analyses of four specimens indicate an amount of berberine varying from 3 per cent. to nearly 8 per cent. The dried stem of *Berberis aristata* is officinal in India, and a tincture is often recommended in the treatment of fever.

IN the island of St. Vincent the Imperial Department of Agriculture for the West Indies controls an agricultural school and a land settlement scheme in addition to the botanic gardens. In the report for 1904–5 Mr. W. N. Sands, the agricultural superintendent, registers a distribution of nearly 30,000 plants, of which more than two-thirds were cacao, and, besides, smaller numbers of sisal bulblets, coffee, lime, and other economic plants. Many of these were distributed to allottees on the land settlement estates who cultivate cacao, canes, cassava, yams, and sweet potatoes. Mr. Sands, reviewing the progress of the cotton industry, has the satisfaction of recording that much of the sea-island cotton was the best produced under the auspices of the British Cotton Growing Association, and had realised seventeen pence per pound.

MR. W. E. COOKE, Government astronomer for Western Australia, has sent us a communication explaining a novel plan that he has adopted for giving more definiteness to the weather forecasts issued in that colony. Each forecast for a definite district is subdivided into specific items, to each of which a figure is attached, "1" representing that the occurrence prognosticated has only the barest possibility of being successful, and so on, up to "5," which indicates that the prediction may be relied upon with almost absolute certainty. Each item of the forecast has therefore a "weight" attached to it; on the whole, Mr. Cooke states that the new method has proved a distinct success, and that while people find that whenever the figure 5 appears the forecast is fulfilled in 99 cases out of 100, they do not feel so disappointed in case of failure when the lower numbers are attached, or as when, under the usual method, equal weight is attached to the whole forecast.

We have received the report of the Falmouth Observatory for the year 1904, reprinted from the seventy-second annual report of the Royal Cornwall Polytechnic Society. This observatory has for many years done excellent work in connection with meteorology and magnetism, as well as by the collection of sea-temperature observations at various places off the coast of Falmouth. The station has for many years been adopted by the Meteorological Office as one of its first-class observatories, and hourly observations or means have been regularly published in the official reports of that office. With regard to magnetism, the Falmouth Observatory has become additionally important, in consequence of the recording magnets at Kew and Greenwich being somewhat affected by the electric trams in those neighbourhoods.

Dr. Alberto Aggazzotti, writing in the *Atti dei Lincei*, xiv., (1), 12, describes some experiments conducted in the physiological laboratory at Turin on the effects of rarefaction on the respiration of the orang-utan. The animal on which the observations were made was brought from Borneo by Count Mario Peracca, who handed it over to Prof. Angelo Mosso for the investigation. It is described as being of good disposition and intelligent; at first it resisted the attempts to place it in the receiver, and tried to destroy the apparatus, but when it realised what was being done, it not only offered no further resistance, but even helped the experimenter in attaching the pneumograph and other necessary apparatus to it. A moderate rarefaction produced no injurious effects provided that the restoration of normal pressure was not effected too rapidly; at 450 millimetres of pressure the animal became more tranquil, at 300 millimetres it fell asleep, while at 270 millimetres it became seriously ill and fell down insensible. The respiration altered in character between 450 millimetres and 470 millimetres with an increase of frequency and a decrease of intensity, while at 300 millimetres it became irregular and spasmodic. These changes fairly well agree with those observed in other animals, particularly man.

Mr. C. Mosley has arranged an edition of White's "Selborne" for students, in which the whole of the letters are classified under subjects, giving the reader all that Gilbert White wrote on one topic under one head. As the subjects will be arranged alphabetically, the work will be one of reference as well as for reading consecutively. Mr. Elliot Stock is to publish the book during the coming season.

We have received a copy of the first fasciculus of vol. xxxv. of the *Mémoires de la Société de Physique et d'Histoire naturelle de Genève*. This part of the transactions contains, with other interesting papers, the president's report for 1904. Dr. Auguste Wartmann-Perrot successively passes in review the administrative events of the year, refers in eulogistic terms to the work of eminent members of the society deceased during the previous year, and recapitulates briefly the scientific subjects discussed in the meetings of the society during 1904. The biographical notices contained in the president's report include those of Charles Soret, renowned for his work in crystallography; of Albert Rilliet, the chemist; and of Wilhelm His, the anatomist. The scientific activity of the society is summarised concisely under subjects, and this part of the report will serve men of science as a full index of the work done by members of the Geneva Society during 1904. The president's statement is a useful account of a good year's work.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in September:—

Sept. 4.		Ceres in opposition to the Sun (Ceres mag. 7·4).
,, ,,	7h. 33m. to 8h. 37m.	Moon occults γ Libræ (mag. 4·1).
,, 8.	10h. 20m.	Minimum of Algol (β Persei).
,, 11.	12h.	Moon in conjunction with Saturn (Saturn 1° 56′ S.).
,, 14.	12h. 42m. to 14h. 11m.	Transit of Jupiter's Sat. III. (Ganymede).
,, 14.	23h.	Mercury at greatest elongation, 17° 54′ W.
,, 15.		Venus. Illuminated portion of disc = 0·787, of Mars = 0·851.
,, 17.	10h. 35m. to 11h. 36m.	Moon occults μ Ceti (mag. 4·4).
,, 18.	9h. 54m. to 10h. 55m.	Moon occults f Tauri (mag. 4·3).
,, 19.	10h. 36m. to 10h. 59m.	Moon occults γ Tauri (mag. 3·9).
,, 19.	13h. 56m. to 14h. 37m.	Moon occults 71 Tauri (mag. 4·6).

Observations of Planets.—The results of a number of recent observations of Saturn and Jupiter are recorded by Mr. Denning in the *Observatory* for August. Using the 12½-inch Calver reflector, some excellent observations of Saturn were obtained during the morning twilight in June and July. The region north of the multiple belt in the northern hemisphere was seen to be the brightest part of the planet—not the equatorial zone, as previously. A small white spot was detected on the N. edge of the great belt on July 6, and estimated to be central at 13h. 40m. A small white spot was seen in the N. temperate zone on the following dates in the positions and at the times stated:—

	Transit time h. m.	Long. System II. °
July 13	13 20	72·7
,, 16	15 35	67·3
,, 21	12 35	69·5

Observing the Great Red Spot on Jupiter on June 24 and July 6, Mr. Denning found it to be central at 15h. 43m. and 15h. 40m. respectively, the corresponding longitudes being 25°·1 and 24°·8. Comparing these longitudes with those published in the April *Observatory*, it is seen that during the period that Jupiter has been too near to the sun to be observable, the motion has conformed precisely with system ii. of the ephemerides based on a rotation period of 9h. 55m. 40·63s. An observation made by the Rev. T. E. R. Phillips confirms the above observation of July 6.

Proper Motions of the Hyades.—A discussion of the proper motions of the Hyades group is the *raison d'être* of No. 14 of the Publications of the Astronomical Laboratory at Groningen. The plates from which the proper motions were derived were obtained by Prof. Donner at Helsingfors and discussed by Profs. Kapteyn and W. de Sitter.

In the introduction to the volume Prof. Kapteyn gives a most interesting discussion of the results obtained by his method of determining proper motions, the method employed in the present case, in which a plate is exposed on a certain area and then packed away for a number of years, exposed again on the same area, and then developed and measured. One of the gravest objections to this method was the fear that the plates would deteriorate during the interval between the two exposures, but Prof. Kapteyn disposes of this objection by stating that not a

single plate of the present series, for which the interval was between four and five years, has had to be rejected. These plates were by Schleussner, on plate glass, and the method of preservation employed by Prof. Donner is explained.

As regards the length of exposure, Prof. Kapteyn states that, whilst it must be chosen in accordance with the particular work contemplated, it must be such as to give at least one hundred easily measured stars on each plate. Another objection raised against this method was that of accuracy as compared with the older method, but from a comparison of the probable errors now obtained with those obtained at Paris and Potsdam in the *carte du ciel* work, Prof. Kapteyn shows that the advantage is with the new method. He further concludes that to attain a given degree of accuracy the labour involved in the present method is *at the very least* seven times smaller than it would be by employing the older method.

The value for the proper motion of the Hyades group adopted by Prof. Donner is

$$\left.\begin{array}{l}\text{In R.A.} +0''{\cdot}0900 = +0{\cdot}00624\text{s.} \\ \text{,, Decl.} -0''{\cdot}0250\end{array}\right\}$$

Reduced to the system given in Publication No. 9, this becomes

$$\begin{array}{l}\text{In R.A.} +0''{\cdot}1107 = +0{\cdot}00767\text{s.} \\ \text{,, Decl.} -0''{\cdot}0259\end{array}$$

which is equivalent to a total proper motion of

$$0''{\cdot}1137 \text{ in position angle } 103^{\circ}{\cdot}17.$$

The general catalogue contains 395 stars, and of these 42 are considered as very probably belonging to the group, 19 are given as "probable," and 16 are regarded as "doubtful."

VARIATIONS OF LATITUDE.—In Nos. 4040–4041 of the *Astronomische Nachrichten* Mr. Kimura, of the International Latitude Observatory at Mizusawa, gives the results of a series of latitude observations made by Mr. Nakano and himself during the year March 28, 1903, to March 31, 1904. Simultaneous observations of four groups were made each night, their principal aims being (1) to examine whether there exists any regular diurnal change of latitude of a measurable quantity; (2) to see how large are the systematic differences between the variation of latitude from this (four groups) series of observations and that from the two groups observations for the international service. The mean declinations and proper motions of the stars observed were taken from the international service work, and the value of the "aberration constant" employed was 20″·512. Great care was taken during the reductions to eliminate accidental errors, and it was found that the personal equation between the two observers was practically negligible. The measures and their reductions are given in detail, and lead to the conclusion that "Any systematic diurnal change of latitude of a measurable quantity cannot exist at all." The subsequent comparison of the results of these observations with those obtained for the international service shows that no systematic differences exist between the four groups observations and the two groups observations made for the international service.

A PROPOSED NEW METHOD FOR DETERMINING THE SOLAR RADIATION.—In No. 4037 of the *Astronomische Nachrichten* Prof. Ceraski proposes a new method whereby the absorption of our atmosphere might be eliminated from observations of the changes in the solar radiation. His proposition is that the light of the telescopic planets should be regularly observed photometrically. If the variation of the solar radiation is great enough, it should be shown in the amount of light reflected by the planets, and a long period of photometric observations of these, such as he proposes, would show the sympathetic variations, whilst, if suitable comparison stars were employed, the differential effect of the earth's atmosphere would not affect the results.

THE CAPE OBSERVATORY.—The opening paragraphs of Sir David Gill's report for the year 1904 deeply lament the loss sustained by the Cape Observatory, and science in general, by the death of Mr. Frank McClean, F.R.S., to whose generosity the observatory owes an important part of its equipment.

The new transit circle has been thoroughly examined and its observers trained during the past twelve months, and it is now ready for routine work. It was found that by using the Repsold-Struve apparatus, in which a travelling wire actuated by clockwork is employed, the magnitude equation in right ascension observations might be almost, if not entirely, eliminated.

Preliminary trials of the new sidereal clock showed that the daily rate never varied more than ±0·03s.; but even this is to be improved by a new arrangement by which the top and bottom of the pendulum will be kept at the same temperature. In order to preserve a more equable temperature inside the case, an enclosing chamber 8 feet square and 13 feet high has been erected about it.

Owing to an unfortunate accident, the driving worm and sector of the Victoria telescope were damaged, and have had to be sent to Sir Howard Grubb for repair. In consequence, the new objective prism has not yet been tested.

A number of observations were made with the transit and equatorial instruments during the year, and 185 plates (containing 117,073 stars) for the Astrographic Catalogue were measured. The total number of plates measured is now 760, containing more than 440,000 star images, corresponding to about 200,000 different stars.

In the astrophysical department 74 star-spectra were photographed, and of these 30 have been measured, and a number of radial velocities deduced.

RECENT ADVANCES IN THE CHEMISTRY OF ALBUMIN.[1]

UNTIL recently, one of the main objects in studying the proteids was to classify them into characteristic groups by the aid of certain reactions. This has now given place to problems of a different nature—the investigation of the quantitative decomposition of the albumin molecule, the progressive degradation and study of the constituent parts, and the determination of the nature of what may be termed the stones of the molecular edifice; finally, the arrangement of these materials in the construction of the albumin molecule.

The task of separating the constituents of the albumin molecule is still far from complete. The reason for this lies in the difficulty connected with their isolation, for they are particularly troublesome to purify. An important advance was made when Emil Fischer discovered the ester method of separating the amino-acids by distilling them in a vacuum. The method bore immediate fruit in the discovery of phenyl-alanine and α-proline (pyrrolidinecarboxylic acid). Fischer has shown, moreover, that certain amino-acids, like alanine, phenyl-alanine, and serine (hydroxyaminopropionic acid) are invariable constituents of the albumin molecule, whilst hydroxy-α-proline, discovered by Fischer, is another widely distributed constituent. Ehrlich has found that the leucine from albumin, long considered a simple substance, is a mixture of at least two bodies. Hopkins and Cole have succeeded in separating tryptophane in a pure state, a substance which had long eluded the attempts of physiologists to isolate, and which they have pronounced to be skatolaminoacetic acid. Skraup has obtained from casein a whole series of new products belonging to the group of diamino- and hydroxyamino-acids—diaminoglutaric acid, diaminoadipic acid, hydroxyaminosebacic acid, and caseanic and caseinic acids of unknown structure.

New substances are constantly being added to the list of what may be termed molecular fragments, which now amount to about twenty individuals.

There still remains the carbohydrate group of albumins. F. Müller has shown that glucosamine from mucine and egg-albumin forms an interesting link between the sugar group and the amino-acids. We are still ignorant of the part played by the carbohydrate in its connection with albumin. We cannot say whether it is a loose combination or a mechanical admixture.

The enormous number of products gives some indication of the complexity of the problem which the study

[1] Abstract of an article by Emil Abderhalden contributed to "Medizinische Klinik," 1905, Nos. 1 and 2.

of albumin affords. Furthermore, before a synthesis can be successfully attempted, it is necessary to know whether these substances are primary or secondary products formed directly or indirectly by the action of the reagent, and here again the field is still untraversed.

Whilst great similarity exists among the constituent parts of the molecule, there is a wide difference in the proportions of each present. The *protamines*, which are obtained from the milt (testicles) of fishes, and represent some of the simplest proteids, contain a large proportion of diamino-acids and a small quantity of monoamino-acids; the kindred *histones*, on the other hand, contain a much smaller proportion of diamino-acids, but the whole group of monoamino-acids. Through a series of gradations we arrive finally at substances like the proteids of silk and elastin, which are exceptionally rich in monoamino-acids.

A comparison of the composition of the individual albumins of food and of the living body leads to the conclusion that in digestion deep-seated changes must occur. Moreover, the view is steadily growing that the albumin molecule forms the basis of the two other important groups of food-stuffs, fats and carbohydrates. The decomposition which certain albumin fragments undergo promises to throw new light on the changes which occur in the organism and on the formation of pathological products.

Granted that the whole series of albumin products were known, their relative arrangement in the molecule would still remain to be discovered. Attempts have been made by using milder reagents to arrest the process of degradation at an earlier stage, and so obtain larger molecular fragments; but great practical difficulties attend the method. Nevertheless, by the labours of Fischer and Bergell a series of no less than four intermediate products between silk and its lowest degradation product have been isolated. First, sericoine; secondly, a substance containing tyrosine; thirdly, one free from tyrosine; and lastly, a compound which probably belongs to the dipeptides mentioned below. This study of partial degradation of the albumin molecule derives increased interest from the behaviour of food albumin in the intestine, which, as Fischer and Abderhalden have shown by their experiments on dogs, probably undergo neither slight nor yet complete decomposition, but partial hydrolysis. It will be an attractive problem to determine how far food albumin may be degraded and yet afford nutriment for the organism.

If the process of decomposition cannot furnish the necessary information about the structure of the albumin molecule, the reverse process of synthesis may effect the desired object. E. Fischer has with wonderful experimental ingenuity and skill successfully followed this path of research. The classical memoirs on the polypeptides have already been referred to in the pages of NATURE. By combining two molecules of amino-acids, the dipeptides, glycyl-glycine, alanyl-alanine, and leucyl-leucine have been obtained, as well as mixed dipeptides, *e.g.* glycyl-alanine, alanyl-glycine, &c. By uniting three and more molecules, tri- and tetra-peptides, &c., are formed. The longest chain of this character is pentaglycine, consisting of a group of five linked glycine molecules.

But, as we have seen, the degradation products of albumin are not all monoamino-acids, but include hydroxy- and diamino-compounds, and peptides of these substances have also been prepared. These products show an unmistakable likeness to the natural peptones. They give the usual reactions—the biuret reaction, precipitation by phosphotungstic acid, and hydrolysis by trypsin. A peculiar interest centres round the different behaviour of the peptides towards the pancreatic ferment. Whereas glycyl-*l*-tyrosine and glycyl-*l*-leucine are easily hydrolysed, glycyl-glycine and glycyl-alanine are unattacked by the ferment.

These experiments, as Fischer has pointed out, are not only useful in indicating the physiologically important compounds among the numerous synthetic materials obtained by him, but show, by the experience so gained, the possibility of discovering the different kinds of linking which exist among the amino-acids of the albumin molecule.

We may anticipate from these investigations some knowledge of the cause whereby different parts of the molecule resist or retard the action of the ferment. J. B. C.

ON THE ORIGIN OF EOLITHS.[1]

FOR some time past the question of the existence of man in different countries during the Tertiary period, based upon flints bearing traces of intentional work, has occupied the lively attention of "prehistorians" in numerous parts of the globe—in France, England, Germany, Russia, Egypt, India, &c.

According to the eminent Belgian geologist, M. Rutot, who has placed himself at the head of this new movement, we must add to the Palæolithic and Neolithic periods a period more ancient still, which has received the name of *Eolithic*. This does not comprise any type of instrument chipped into an *intentional form*, but only natural forms utilised at once. These primitive and rough tools have received the name of *eoliths*. It is believed that they may be recognised by the presence of secondary work (*retouches*), that is to say, the removal of small flakes in apparently a systematic manner, in accordance with the needs of the case, or resulting from the wear of the flint by use.

An enormous quantity of eoliths are found in the Quaternary gravels mixed with instruments of determinate and classic forms. In the gravels of the north of France and of Belgium, M. Rutot has described several industries of this kind, the *Reutelian*, the *Mafflian*, the *Mesvinian*, &c. But such objects are equally met with in beds of far greater antiquity; the chipped stones of the Oligocene of Thenay, of the Miocene of Otta and Aurillac, of the Pliocene of England, &c., are eoliths; and here the question becomes far more grave, inasmuch as the adepts in the new theories rely on these facts to admit the existence of man or his immediate precursor during the Tertiary period.

For twenty years I have not ceased to combat these theories; first, because it appeared to me to be imprudent to admit the existence of Tertiary man in the absence of all direct, that is to say, in the absence of osteological evidence, and secondly, because I have always been convinced that the eoliths are due to natural causes. I had, indeed, had occasion to meet with them in all the ancient alluvia of torrential character in which flints were present. In Auvergne, and in the Velay, in the course of my explorations in connection with the geological map, I had found them at numerous points in the midst of Oligocene or Miocene beds occupying thousands of square kilometres in extent. I asked myself how experiments could be undertaken to solve the problem of the eoliths, when M. Laville, of the École des Mines, brought before M. Cartailhac, correspondent of the institute, Dr. Obermaier, and myself some experiments carried on daily, but unintentionally, in an industrial establishment.

There are in the Commune of Guerville, near Mantes, some works in which cement is made from a mixture of chalk and plastic clay. The chalk, as usual, contains blocks of flint which are rejected by the diggers. Trucks convey the chalk from the quarry to the neighbouring works, and deliver it with a certain quantity of clay into circular vats called *délayeurs*. These are about 5 metres in diameter and 1·40 metres in depth. The water which serves them arrives by pipes, and is discharged through lateral sieves, carrying with it the finest particles of the mixture of chalk and clay. The water is set in motion by a horizontal wheel, above the level of the water, but from its spokes are suspended harrows (*herses*) of cast-iron dipping into the water; the speed of rotation of the wheel is about 4 metres at its circumference.

The water is thus driven into a tumultuous movement, which carries away not only the particles of chalk and clay, but also a certain number of flints which have escaped the attention of the workmen, and have been thrown into the vats together with the chalk. These flints are therefore subjected to blows one against the other which during a period of twenty-nine hours must be extremely numerous. When the machinery is stopped, the flints remain at the bottom of the vat, where they are covered by a coating of chalk. They are taken out of the vats to be washed and placed in heaps, as they are useful for making concrete.

Now these bits of flint that while in the vats have

[1] Translation of a paper by M. Marcellin Boule in the *Comptes rendus* of the Paris Academy of Sciences (June 26).

undergone the dynamic action of an artificial whirlpool in all points comparable with the dynamic action of a torrential current of water, present all the characteristics of the ancient river-gravels; it is easy to find among them, after a few minutes' search, all the most characteristic forms of eoliths, such as are given as typical. My colleagues and I have been able to make a collection of flints admirably *retouchés*, identical with the forms called by M. Rutot hammer-stones, planes, notched flints, &c. We have also collected flints showing the cone of percussion, which is generally regarded as an infallible mark of intentional fashioning.

THE BRITISH ASSOCIATION.

Inaugural Address by Prof. G. H. Darwin, M.A., LL.D., Ph.D., F.R.S., President of the Association.

Part II.[1]

Thus far we have been concerned with the almost inconceivably minute, and I now propose to show that similar conditions prevail on a larger scale.

Many geological problems might well be discussed from my present point of view, yet I shall pass them by, and shall proceed at once to Astronomy, beginning with the smallest cosmical scale of magnitude, and considering afterwards the larger celestial phenomena.

The problems of cosmical evolution are so complicated that it is well to conduct the attack in various ways at the same time. Although the several theories may seem to some extent discordant with one another, yet, as I have already said, we ought not to scruple to carry each to its logical conclusion. We may be confident that in time the false will be eliminated from each theory, and when the true alone remains the reconciliation of apparent disagreements will have become obvious.

The German astronomer Bode long ago propounded a simple empirical law concerning the distances at which the several planets move about the sun. It is true that the planet Neptune, discovered subsequently, was found to be considerably out of the place which would be assigned to it by Bode's law, yet his formula embraces so large a number of cases with accuracy that we are compelled to believe that it arises in some manner from the primitive conditions of the planetary system.

The explanation of the causes which have led to this simple law as to the planetary distances presents an interesting problem, and, although it is still unsolved, we may obtain some insight into its meaning by considering what I have called a working model of ideal simplicity.

Imagine then a sun round which there moves in a circle a single large planet. I will call this planet Jove, because it may be taken as a representative of our largest planet, Jupiter. Suppose next that a meteoric stone or small planet is projected in any perfectly arbitrary manner in the same plane in which Jove is moving; then we ask how this third body will move. The conditions imposed may seem simple, yet the problem has so far overtaxed the powers of the mathematician that nothing approaching a general answer to our question has yet been given. We know, however, that under the combined attractions of the sun and Jove the meteoric stone will in general describe an orbit of extraordinary complexity, at one time moving slowly at a great distance from both the sun and Jove, at other times rushing close past one or other of them. As it grazes past Jove or the sun it may often but just escape a catastrophe, but a time will come at length when it runs its chances too fine and comes into actual collision. The individual career of the stone is then ended by absorption, and of course by far the greater chance is that it will find its Nirvana by absorption in the sun.

Next let us suppose that instead of one wandering meteoric stone or minor planet there are hundreds of them, moving initially in all conceivable directions. Since they are all supposed to be very small, their mutual attractions will be insignificant, and they will each move almost as though they were influenced only by the sun and Jove.

[1] Delivered at Johannesburg on August 30. The first part of the Address, delivered at Cape Town on August 15, appeared in Nature of August 17.

Most of these stones will be absorbed by the sun, and the minority will collide with Jove.

When we inquire how long the career of a stone may be, we find that it depends on the direction and speed with which it is started, and that by proper adjustment the delay of the final catastrophe may be made as long as we please. Thus by making the delay indefinitely long we reach the conception of a meteoric stone which moves so as never to come into collision with either body.

There are, therefore, certain perpetual orbits in which a meteoric stone or minor planet may move for ever without collision. But when such an immortal career has been discovered for our minor planet, it still remains to discover whether the slightest possible departure from the prescribed orbit will become greater and greater and ultimately lead to a collision with the sun or Jove, or whether the body will travel so as to cross and re-cross the exact perpetual orbit, always remaining close to it. If the slightest departure inevitably increases as time goes on, the orbit is unstable; if, on the other hand, it only leads to a slight waviness in the path described, it is stable.

We thus arrive at another distinction: there are perpetual orbits, but some, and indeed most, are unstable, and these do not offer an immortal career for a meteoric stone; and there are other perpetual orbits which are stable or persistent. The unstable ones are those which succumb in the struggle for life, and the stable ones are the species adapted to their environment.

If, then, we are given a system of a sun and large planet, together with a swarm of small bodies moving in all sorts of ways, the sun and planet will grow by accretion, gradually sweeping up the dust and rubbish of the system, and there will survive a number of small planets and satellites moving in certain definite paths. The final outcome will be an orderly planetary system in which the various orbits are arranged according to some definite law.

But the problem presented even by a system of such ideal simplicity is still far from having received a complete solution. No general plan for determining perpetual orbits has yet been discovered, and the task of discriminating the stable from the unstable is arduous. But a beginning has been made in the determination of some of the zones surrounding the sun and Jove in which stable orbits are possible, and others in which they are impossible. There is hardly room for doubt that if a complete solution for our solar system were attainable, we should find that the orbits of the existing planets and satellites are numbered amongst the stable perpetual orbits, and should thus obtain a rigorous mechanical explanation of Bode's law concerning the planetary distances.

It is impossible not to be struck by the general similarity between the problem presented by the corpuscles moving in orbits in the atom, and that of the planets and satellites moving in a planetary system. It may not, perhaps, be fanciful to imagine that some general mathematical method devised for solving a problem of cosmical evolution may find another application to miniature atomic systems, and may thus lead onward to vast developments of industrial mechanics. Science, however diverse its aims, is a whole, and men of science do well to impress on the captains of industry that they should not look askance on those branches of investigation which may seem for the moment far beyond any possibility of practical utility.

You will remember that I discussed the question as to whether the atomic communities of corpuscles could be regarded as absolutely eternal, and that I said that the analogy of other moving systems pointed to their ultimate mortality. Now the chief analogy which I had in my mind was that of a planetary system.

The orbits of which I have spoken are only perpetual when the bodies are infinitesimal in mass, and meet with no resistance as they move. Now the infinitesimal body does not exist, and both Lord Kelvin and Poincaré concur in holding that disturbance will ultimately creep in to any system of bodies moving even in so-called stable orbits; and this is so even apart from the resistance offered to the moving bodies by any residual gas there may be scattered through space. The stability is therefore only relative, and a planetary system contains the seeds of its own destruction. But this ultimate fate need not disturb

us either practically or theoretically, for the solar system contains in itself other seeds of decay which will probably bear fruit long before the occurrence of any serious disturbance of the kind of which I speak.

Before passing on to a new topic I wish to pay a tribute to the men to whom we owe the recent great advances in theoretical dynamical astronomy. As treated by the master-hands of Lagrange and Laplace and their successors, this branch of science hardly seemed to afford scope for any great new departure. But that there is always room for discovery, even in the most frequented paths of knowledge, was illustrated when, nearly thirty years ago, Hill of Washington proposed a new method of treating the theory of the moon's motion in a series of papers which have become classical. I have not time to speak of the enormous labour and great skill involved in the completion of Hill's Lunar Theory, by Ernest Brown, whom I am glad to number amongst my pupils and friends; for I must confine myself to other aspects of Hill's work.

The title of Hill's most fundamental paper, namely, "On Part of the Motion of the Lunar Perigee," is almost comic in its modesty, for who would suspect that it contains the essential points involved in the determination of perpetual orbits and their stability? Probably Hill himself did not fully realise at the time the full importance of what he had done. Fortunately he was followed by Poincaré, who not only saw its full meaning but devoted his incomparable mathematical powers to the full theoretical development of the point of view I have been laying before you.

Other mathematicians have also made contributions to this line of investigation, amongst whom I may number my friend Mr. Hough, chief assistant at the Royal Observatory of Cape Town, and myself. But without the work of our two great forerunners we should still be in utter darkness, and it would have been impossible to give even this slight sketch of a great subject.

The theory which I have now explained points to the origin of the sun and planets from gradual accretions of meteoric stones, and it makes no claim to carry the story back behind the time when there was already a central condensation or sun about which there circled another condensation or planet. But more than a century ago an attempt had already been made to re-construct the history back to a yet remoter past, and, as we shall see, this attempt was based upon quite a different supposition as to the constitution of the primitive solar system. I myself believe that the theory I have just explained, as well as that to which I am coming, contains essential elements of truth, and that the apparent discordances will some day be reconciled. The theory of which I speak is the celebrated nebular hypothesis, first suggested by the German philosopher Kant, and later re-stated independently and in better form by the French mathematician Laplace.

Laplace traced the origin of the solar system to a nebula or cloud of rarefied gas congregated round a central condensation which was ultimately to form the sun. The whole was slowly rotating about an axis through its centre, and, under the combined influences of rotation and of the mutual attraction of the gas, it assumed a globular form, slightly flattened at the poles. The justifiability of this supposition is confirmed by the observations of astronomers, for they find in the heavens many nebulæ, while the spectroscope proves that their light at any rate is derived from gas. The primeval globular nebula is undoubtedly a stable or persistent figure, and thus Laplace's hypothesis conforms to the general laws which I have attempted to lay down.

The nebula must have gradually cooled by radiation into space, and as it did so the gas must necessarily have lost some of its spring or elasticity. This loss of power of resistance then permitted the gas to crowd more closely towards the central condensation, so that the nebula contracted. The contraction led to two results, both inevitable according to the laws of mechanics: first, the central condensation became hotter; and, secondly, the speed of its rotation became faster. The accelerated rotation led to an increase in the amount of polar flattening, and the nebula at length assumed the form of a lens, or of a disc thicker in the middle than at the edges. Assuming the existence of the primitive nebula, the hypothesis may be accepted thus far as practically certain.

From this point, however, doubt and difficulty enter into the argument. It is supposed that the nebula became so much flattened that it could not subsist as a continuous aggregation of gas, and a ring of matter detached itself from the equatorial regions. The central portions of the nebula, when relieved of the excrescence, resumed the more rounded shape formerly possessed by the whole. As the cooling continued the central portion in its turn became excessively flattened through the influence of its increased rotation; another equatorial ring then detached itself, and the whole process was repeated as before. In this way the whole nebula was fissured into a number of rings surrounding the central condensation, the temperature of which must by then have reached incandescence.

Each ring then aggregated itself round some nucleus which happened to exist in its circumference, and so formed a subordinate nebula. Passing through a series of transformations, like its parent, this nebula was finally replaced by a planet with attendant satellites.

The whole process forms a majestic picture of the history of our system. But the mechanical conditions of a rotating nebula are too complex to admit, as yet, of complete mathematical treatment; and thus, in discussing this theory, the physicist is compelled in great measure to adopt the qualitative methods of the biologist, rather than the quantitative ones which he would prefer.

The telescope seems to confirm the general correctness of Laplace's hypothesis. Thus, for example, the great nebula in Andromeda presents a grand illustration of what we may take to be a planetary system in course of formation. In it we see the central condensation surrounded by a more or less ring-like nebulosity, and in one of the rings there appears to be a subordinate condensation.

Nevertheless it is hardly too much to say that every stage in the supposed process presents to us some difficulty or impossibility. Thus we ask whether a mass of gas of almost inconceivable tenuity can really rotate all in one piece, and whether it is not more probable that there would be a central whirlpool surrounded by more slowly-moving parts. Again, is there any sufficient reason to suppose that a series of intermittent efforts would lead to the detachment of distinct rings, and is not a continuous outflow of gas from the equator more probable?

The ring of Saturn seems to have suggested the theory to Laplace; but to take it as a model leads us straight to a quite fundamental difficulty. If a ring of matter ever concentrates under the influence of its mutual attraction, it can only do so round the centre of gravity of the whole ring. Therefore the matter forming an approximately uniform ring, if it concentrates at all, can only fall in on the parent planet and be re-absorbed. Some external force other than the mutual attraction of the matter forming the ring, and therefore not provided by the theory, seems necessary to effect the supposed concentration. The only way of avoiding this difficulty is to suppose the ring to be ill-balanced or lop-sided; in this case, provided the want of balance is pronounced enough, concentration will take place round a point inside the ring but outside the planet. Many writers assume that the present distances of the planets preserve the dimensions of the primitive rings; but the argument that a ring can only aggregate about its centre of gravity, which I do not recollect to have seen before, shows that such cannot be the case.

The concentration of an ill-balanced or broken ring on an interior point would necessarily generate a planet with direct rotation—that is to say, rotating in the same direction as the earth. But several writers, and notably Faye, endeavour to show—erroneously as I think—that a retrograde rotation should be normal, and they are therefore driven to make various complicated suppositions to explain the observed facts. But I do not claim to have removed the difficulty, only to have shifted it; for the satellites of Neptune, and presumably the planet itself, have retrograde rotations; and, lastly, the astonishing discovery has just been made by William Pickering of a ninth retrograde satellite of Saturn, while the rotations of the eight other satellites, of the ring and of the planet itself, are direct. Finally, I express a doubt as to whether the telescope

does really exactly confirm the hypothesis of Laplace, for I imagine that what we see indicates a spiral rather than a ring-like division of nebulæ.[1]

This is not the time to pursue these considerations further, but enough has been said to show that the nebular hypothesis cannot be considered as a connected intelligible whole, however much of truth it may contain.

In the first theory which I sketched as to the origin of the sun and planets, we supposed them to grow by the accretions of meteoric wanderers in space, and this hypothesis is apparently in fundamental disagreement with the conception of Laplace, who considered the transformations of a continuous gaseous nebula. Some years ago a method occurred to me by which these two discordant schemes of origin might perhaps be reconciled. A gas is not really continuous, but it consists of a vast number of molecules moving in all directions with great speed and frequently coming into collision with one another. Now I have ventured to suggest that a swarm of meteorites would, by frequent collisions, form a medium endowed with so much of the mechanical properties of a gas as would satisfy Laplace's conditions. If this is so, a nebula may be regarded as a quasi-gas, the molecules of which are meteorites. The gaseous luminosity which undoubtedly is sent out by nebulæ would then be due only to incandescent gas generated by the clash of meteorites, while the dark bodies themselves would remain invisible. Sir Norman Lockyer finds spectroscopic evidence which led him long ago to some such view as this, and it is certainly of interest to find in his views a possible means of reconciling two apparently totally discordant theories.[2] However, I do not desire to lay much stress on my suggestion, for without doubt a swarm of meteors could only maintain the mechanical properties of a gas for a limited time, and, as pointed out by Prof. Chamberlin, it is difficult to understand how a swarm of meteorites moving indiscriminately in every direction could ever have come into existence. But my paper may have served to some extent to suggest to Chamberlin his recent modification of the nebular hypothesis, in which he seeks to reconcile Laplace's view with a meteoritic origin of the planetary system.[3]

We have seen that, in order to explain the genesis of planets according to Laplace's theory, the rings must be ill-balanced or even broken. If the ring were so far from being complete as only to cover a small segment of the whole circumference, the true features of the occurrences in the births of planets and satellites might be better represented by conceiving the detached portion of matter to have been more or less globular from the first, rather than ring-shaped. Now this idea introduces us to a group of researches whereby mathematicians have sought to explain the birth of planets and satellites in a way which might appear, at first sight, to be fundamentally different from that of Laplace.

The solution of the problem of evolution involves the search for those persistent or stable forms which biologists would call species. The species of which I am now going to speak may be grouped in a family, which comprises all those various forms which a mass of rotating liquid is capable of assuming under the conjoint influences of gravitation and rotation. If the earth were formed throughout of a liquid of the same density, it would be one of the species of this family; and indeed these researches date back to the time of Newton, who was the first to explain the figures of planets.

The ideal liquid planets we are to consider must be regarded as working models of actuality, and inasmuch as the liquid is supposed to be incompressible, the conditions depart somewhat widely from those of reality. Hence, when the problem has been solved, much uncertainty remains as to the extent to which our conclusions will be applicable to actual celestial bodies.

We begin, then, with a rotating liquid planet like the earth, which is the first stable species of our family. We next impart in imagination more rotation to this planet, and find by mathematical calculation that its power of resistance to any sort of disturbance is less than it was. In other words, its stability declines with increased rotation, and at length we reach a stage at which the stability just vanishes. At this point the shape is a transitional one, for it is the beginning of a new species with different characteristics from the first, and with a very feeble degree of stability or power of persistence. As a still further amount of rotation is imparted, the stability of the new species increases to a maximum and then declines until a new transitional shape is reached and a new species comes into existence. In this way we pass from species to species with an ever-increasing amount of rotation.

The first or planetary species has a circular equator like the earth; the second species has an oval equator, so that it is something like an egg spinning on its side on a table; in the third species we find that one of the two ends of the egg begins to swell, and that the swelling gradually becomes a well-marked protrusion or filament. Finally the filamentous protrusion becomes bulbous at its end, and is only joined to the main mass of liquid by a gradually thinning neck. The neck at length breaks, and we are left with two separated masses which may be called planet and satellite. It is fair to state that the actual rupture into two bodies is to some extent speculative, since mathematicians have hitherto failed to follow the whole process to the end.

In this ideal problem the successive transmutations of species are brought about by gradual additions to the amount of rotation with which the mass of liquid is endowed. It might seem as if this continuous addition to the amount of rotation were purely arbitrary and could have no counterpart in nature. But real bodies cool and contract in cooling, and, since the scale of magnitude on which our planet is built is immaterial, contraction will produce exactly the same effect on shape as augmented rotation. I must ask you, then, to believe that the effects of an apparently arbitrary increase of rotation may be produced by cooling.

The figures which I succeeded in drawing, by means of rigorous calculation, of the later stages of this course of evolution, are so curious as to remind one of some such phenomenon as the protrusion of a filament of protoplasm from a mass of living matter, and I suggest that we may see in this almost life-like process the counterpart of at least one form of the birth of double stars, planets, and satellites.

As I have already said, Newton determined the first of these figures; Jacobi found the second, and Poincaré indicated the existence of the third, in a paper which is universally regarded as one of the masterpieces of applied mathematics; finally I myself succeeded in determining the exact form of Poincaré's figure, and in proving that it is a true stable shape.

My Cambridge colleague Jeans has also made an interesting contribution to the subject by discussing a closely analogous problem, and he has besides attacked the far more difficult case where the rotating fluid is a compressible gas. In this case also he finds a family of types, but the conception of compressibility introduced a new set of considerations in the transitions from species to species. The problem is, however, of such difficulty that he had to rest content with results which were rather qualitative than strictly quantitative.

This group of investigations brings before us the process of the birth of satellites in a more convincing form than was possible by means of the general considerations adduced by Laplace. It cannot be doubted that the supposed Laplacian sequence of events possesses a considerable element of truth, yet these latter schemes of transformation can be followed in closer detail. It seems, then, probable that both processes furnish us with crude models of reality, and that in some cases the first and in others the second is the better representative.

The moon's mass is one-eightieth of that of the earth, whereas the mass of Titan, the largest satellite in the solar system, is 1/4600 of that of Saturn. On the ground of this great difference between the relative magnitudes of all other satellites and of the moon, it is not unreasonable to suppose that the mode of separation of the moon from the earth may also have been widely different. The

[1] Prof. Chamberlin, of Chicago, has recently proposed a modified form of the nebular hypothesis, in which he contends that the spiral form is normal. See "Year Book," No. 3, for 1904, of the Carnegie Institution of Washington, pp. 195–258.

[2] Newcomb considers the objections to Lockyer's theory insuperable. See p. 190 of "The Stars." (London: John Murray, 1904.)

[3] See preceding reference to Chamberlin's paper.

theory of which I shall have next to speak claims to trace the gradual departure of the moon from an original position not far removed from the present surface of the earth. If this view is correct, we may suppose that the detachment of the moon from the earth occurred as a single portion of matter, and not as a concentration of a Laplacian ring.

If a planet is covered with oceans of water and air, or if it is formed of plastic molten rock, tidal oscillations must be generated in its mobile parts by the attractions of its satellites and of the sun. Such movements must be subject to frictional resistance, and the planet's rotation will be slowly retarded by tidal friction in much the same way that a fly-wheel is gradually stopped by any external cause of friction. Since action and reaction are equal and opposite, the action of the satellites on the planet, which causes the tidal friction of which I speak, must correspond to a reaction of the planet on the motion of the satellites.

At any moment of time we may regard the system composed of the rotating planet with its attendant satellite as a stable species of motion, but the friction of the tides introduces forces which produce a continuous, although slow, transformation in the configuration. It is, then, clearly of interest to trace backwards in time the changes produced by such a continuously acting cause, and to determine the initial condition from which the system of planet and satellite must have been slowly degrading. We may also look forward, and discover whither the transformation tends.

Let us consider, then, the motion of the earth and moon revolving in company round the sun, on the supposition that the friction of the tides in the earth is the only effective cause of change. We are, in fact, to discuss a working model of the system, analogous to those of which I have so often spoken before.

This is not the time to attempt a complete exposition of the manner in which tidal friction gives rise to the action and reaction between planet and satellite, nor shall I discuss in detail the effects of various kinds which are produced by this cause. It must suffice to set forth the results in their main outlines, and, as in connection with the topic of evolution retrospect is perhaps of greater interest than prophecy, I shall begin with the consideration of the past.

At the present time the moon, moving at a distance of 240,000 miles from the earth, completes her circuit in twenty-seven days. Since a day is the time of one rotation of the earth on its axis, the angular motion of the earth is twenty-seven times as rapid as that of the moon.

Tidal friction acts as a brake on the earth, and therefore we look back in retrospect to times when the day was successively twenty-three, twenty-two, twenty-one of our present hours in length, and so on backward to still shorter days. But during all this time the reaction on the moon was at work, and it appears that its effect must have been such that the moon also revolved round the earth in a shorter period than it does now; thus the month also was shorter in absolute time than it now is. These conclusions are absolutely certain, although the effects on the motions of the earth and of the moon are so gradual that they can only doubtfully be detected by the most refined astronomical measurements.

We take the "day," regarding it as a period of variable length, to mean the time occupied by a single rotation of the earth on its axis; and the "month," likewise variable in absolute length, to mean the time occupied by the moon in a single revolution round the earth. Then, although there are now twenty-seven days in a month, and although both day and month were shorter in the past, yet there is, so far, nothing to tell us whether there were more or fewer days in the month in the past. For if the day is now being prolonged more rapidly than the month, the number of days in the month was greater in the past than it now is; and if the converse were true, the number of days in the month was less.

Now it appears from mathematical calculation that the day must now be suffering a greater degree of prolongation than the month, and accordingly in retrospect we look back to a time when there were more days in the month than at present. That number was once twenty-nine, in place of the present twenty-seven; but the epoch of twenty-nine days in the month is a sort of crisis in the history of moon and earth, for yet earlier the day was shortening less rapidly than the month. Hence, earlier than the time when there were twenty-nine days in the month, there was a time when there was a reversion to the present smaller number of days.

We thus arrive at the curious conclusion that there is a certain number of days to the month, namely twenty-nine, which can never have been exceeded, and we find that this crisis was passed through by the earth and moon recently; but, of course, a recent event in such a long history may be one which happened some millions of years ago.

Continuing our retrospect beyond this crisis, both day and month are found continuously shortening, and the number of days in the month continues to fall. No change in conditions which we need pause to consider now supervenes, and we may ask at once, what is the initial stage to which the gradual transformation points? I say, then, that on following the argument to its end the system may be traced back to a time when the day and month were identical in length, and were both only about four or five of our present hours. The identity of day and month means that the moon was always opposite to the same side of the earth; thus at the beginning the earth always presented the same face to the moon, just as the moon now always shows the same face to us. Moreover, when the month was only some four or five of our present hours in length the moon must have been only a few thousand miles from the earth's surface—a great contrast with the present distance of 240,000 miles.

It might well be argued from this conclusion alone that the moon separated from the earth more or less as a single portion of matter at a time immediately antecedent to the initial stage to which she has been traced. But there exists a yet more weighty argument favourable to this view, for it appears that the initial stage is one in which the stability of the species of motion is tottering, so that the system presents the characteristic of a transitional form, which we have seen to denote a change of type or species in a previous case.

In discussing the transformations of a liquid planet we saw the tendency of the single mass to divide into two portions, although we failed to extend the rigorous argument back to the actual moment of separation; and now we seem to reach a similar crisis from the opposite end, when in retrospect we trace back the system to two masses of unequal size in close proximity with one another. The argument almost carries conviction with it, but I have necessarily been compelled to pass over various doubtful points.

Time is wanting to consider other subjects worthy of notice which arise out of this problem, yet I wish to point out that the earth's axis must once have been less tilted over with reference to the sun than it is now, so that the obliquity of the ecliptic receives at least a partial explanation. Again, the inclination of the moon's orbit may be in great measure explained; and, lastly, the moon must once have moved in a nearly circular path. The fact that tidal friction is competent to explain the eccentricity of an orbit has been applied in a manner to which I shall have occasion to return hereafter.

In my paper on this subject I summed up the discussion in the following words, which I still see no reason to retract:—

"The argument reposes on the imperfect rigidity of solids, and on the internal friction of semi-solids and fluids; these are *verae causae*. Thus changes of the kind here discussed must be going on, and must have gone on in the past. And for this history of the earth and moon to be true throughout it is only necessary to postulate a sufficient lapse of time, and that there is not enough matter diffused through space materially to resist the motions of the moon and earth in perhaps several hundred million years.

"It hardly seems too much to say that granting these two postulates and the existence of a primeval planet, such as that above described, then a system would necessarily be developed which would bear a strong resemblance to our own.

"A theory, reposing on *verae causae*, which brings into

quantitative correlation the lengths of the present day and month, the obliquity of the ecliptic, and the inclination and eccentricity of the lunar orbit, must, I think, have strong claims to acceptance."[1]

We have pursued the changes into the past, and I will refer but shortly to the future. The day and month are both now lengthening, but the day changes more quickly than the month. Thus the two periods tend again to become equal to one another, and it appears that when that goal is reached both day and month will be as long as fifty-five of our present days. The earth will then always show the same face to the moon, just as it did in the remotest past. But there is a great contrast between the ultimate and initial conditions, for the ultimate stage, with day and month both equal to fifty-five of our present days, is one of great stability in contradistinction to the vanishing stability which we found in the initial stage.

Since the relationship between the moon and earth is a mutual one, the earth may be regarded as a satellite of the moon, and if the moon rotated rapidly on her axis, as was probably once the case, the earth must at that time have produced tides in the moon. The mass of the moon is relatively small, and the tides produced by the earth would be large; accordingly the moon would pass through the several stages of her history much more rapidly than the earth. Hence it is that the moon has already advanced to that condition which we foresee as the future fate of the earth, and now always shows to us the same face.

If the earth and moon were the only bodies in existence, this ultimate stage when the day and month were again identical in length would be one of absolute stability, and therefore eternal; but the presence of the sun introduces a cause for yet further changes. I do not, however, propose to pursue the history to this yet remoter futurity, because our system must contain other seeds of decay which will probably bear fruit before these further transformations could take effect.

If, as has been argued, tidal friction has played so important a part in the history of the earth and moon, it might be expected that the like should be true of the other planets and satellites, and of the planets themselves in their relationship to the sun. But numerical examination of the several cases proves conclusively that this cannot have been the case. The relationship of the moon to the earth is in fact quite exceptional in the solar system, and we have still to rely on such theories as that of Laplace for the explanation of the main outlines of the solar system.

I have as yet only barely mentioned the time occupied by the sequence of events sketched out in the various schemes of cosmogony, and the question of cosmical time is a thorny and controversial one.

Our ideas are absolutely blank as to the time requisite for the evolution according to Laplace's nebular hypothesis. And again, if we adopt the meteoritic theory, no estimate can be formed of the time required even for an ideal sun, with its attendant planet Jove, to sweep up the wanderers in space. We do know, indeed, that there is a continuous gradation from stable to unstable orbits, so that some meteoric stones may make thousands or millions of revolutions before meeting their fate by collision. Accordingly, not only would a complete absorption of all the wanderers occupy an infinite time, but also the amount of the refuse of the solar system still remaining scattered in planetary space is unknown. And, indeed, it is certain that the process of clearance is still going on, for the earth is constantly meeting meteoric stones, which, penetrating the atmosphere, become luminous through the effects of the frictional resistance with which they meet.

All we can assert of such theories is that they demand enormous intervals of time as estimated in years.

The theory of tidal friction stands alone amongst these evolutionary speculations in that we can establish an exact but merely relative time-scale for every stage of the process. It is true that the value in years of the unit of time remains unknown, and it may be conjectured that the unit has varied to some extent as the physical condition of the earth has gradually changed.

1 *Phil. Trans.*, pt. ii., 1880, p. 883.

It is, however, possible to determine a period in years which must be shorter than that in which the whole history is comprised. If at every moment since the birth of the moon tidal friction had always been at work in such a way as to produce the greatest possible effect, then we should find that sixty million years would be consumed in this portion of evolutionary history. The true period must be much greater, and it does not seem extravagant to suppose that 500 to 1000 million years may have elapsed since the birth of the moon.

Such an estimate would not seem extravagant to geologists who have, in various ways, made exceedingly rough determinations of geological periods. One such determination is derived from measures of the thickness of deposited strata, and the rate of the denudation of continents by rain and rivers. I will not attempt to make any precise statement on this head, but I imagine that the sort of unit with which the geologist deals is 100 million years, and that he would not consider any estimate involving from one to twenty of such units as unreasonable.

Mellard Reade has attempted to determine geological time by certain arguments as to the rate of denudation of limestone rocks, and arrives at the conclusion that geological history is comprised in something less than 600 million years.[1] The uncertainty of this estimate is wide, and I imagine that geologists in general would not lay much stress on it.

Joly has employed a somewhat similar, but probably less risky, method of determination.[2] When the earth was still hot, all the water of the globe must have existed in the form of steam, and when the surface cooled that steam must have condensed as fresh water. Rain then washed the continents and carried down detritus and soluble matter to the seas. Common salt is the most widely diffused of all such soluble matter, and its transit to the sea is an irreversible process, because the evaporation of the sea only carries back to the land fresh water in the form of rain. It seems certain, then, that the saltness of the sea is due to the washing of the land throughout geological time.

Rough estimates may be formed of the amount of river water which reaches the sea in a year, and the measured saltness of rivers furnishes a knowledge of the amount of salt which is thus carried to the sea. A closer estimate may be formed of the total amount of salt in the sea. On dividing the total amount of salt by the annual transport Joly arrives at the quotient of about 100 millions, and thence concludes that geological history has occupied 100 million years. I will not pause to consider the several doubts and difficulties which arise in the working out of this theory. The uncertainties involved must clearly be considerable, yet it seems the best of all the purely geological arguments whence we derive numerical estimates of geological time. On the whole I should say that pure geology points to some period intermediate between 50 and 1000 millions of years, but the upper limit is more doubtful than the lower. Thus far we do not find anything which renders the tidal theory of evolution untenable.

But the physicists have formed estimates in other ways which, until recently, seemed to demand in the most imperative manner a far lower scale of time. According to all theories of cosmogony, the sun is a star which became heated in the process of its condensation from a condition of wide dispersion. When a meteoric stone falls into the sun the arrest of its previous motion gives rise to heat, just as the blow of a horse's shoe on a stone makes a spark. The fall of countless meteoric stones, or the condensation of a rarefied gas, was supposed to be the sole cause of the sun's high temperature.

Since the mass of the sun is known, the total amount of the heat generated in it, in whatever mode it was formed, can be estimated with a considerable amount of precision. The heat received at the earth from the sun can also be measured with some accuracy, and hence it is a mere matter of calculation to determine how much heat the sun sends out in a year. The total heat which can have been generated in the sun divided by the annual

2 "An Estimate of the Geological Age of the Earth," *Trans. Roy. Dub. Soc.*, vol. vii. series iii., 1902, pp. 23–66.

output gives a quotient of about 20 millions. Hence it seemed to be imperatively necessary that the whole history of the solar system should be comprised within some 20 millions of years.

This argument, which is due to Helmholtz, appeared to be absolutely crushing, and for the last forty years the physicists have been accustomed to tell the geologists that they must moderate their claims. But for myself I have always believed that the geologists were more nearly correct than the physicists, notwithstanding the fact that appearances were so strongly against them.

And now, at length, relief has come to the strained relations between the two parties, for the recent marvellous discoveries in physics show that concentration of matter is not the only source from which the sun may draw its heat.

Radium is a substance which is perhaps millions of times more powerful than dynamite. Thus it is estimated that an ounce of radium would contain enough power to raise 10,000 tons a mile above the earth's surface. Another way of stating the same estimate is this: the energy needed to tow a ship of 12,000 tons a distance of six thousand sea miles at 15 knots is contained in 22 ounces of radium. The *Saxon* probably burns five or six thousand tons of coal on a voyage of approximately the same length. Again, M. and Mme. Curie have proved that radium actually gives out heat,[1] and it has been calculated that a small proportion of radium in the sun would suffice to explain its present radiation. Other lines of argument tend in the same direction.[2]

Now we know that the earth contains radio-active materials, and it is safe to assume that it forms in some degree a sample of the materials of the solar system. Hence it is almost certain that the sun is radio-active also; and besides it is not improbable that an element with so heavy an atom as radium would gravitate more abundantly to the central condensation than to the outlying planets. In this case the sun should contain a larger proportion of radio-active material than the earth.

This branch of science is as yet but in its infancy, but we already see how unsafe it is to dogmatise on the potentialities of matter.

It appears, then, that the physical argument is not susceptible of a greater degree of certainty than that of the geologists, and the scale of geological time remains in great measure unknown.

I have now ended my discussion of the solar system, and must pass on to the wider fields of the stellar universe.

Only a few thousand stars are visible with the unaided eye, but photography has revealed an inconceivably vast multitude of stars and nebulæ, and every improvement in that art seems to disclose yet more and more. About twenty years ago the number of photographic objects in the heavens was roughly estimated at about 170 millions, and some ten years later it had increased to about 400 millions. Although Newcomb, in his recent book on "The Stars," refrains even from conjecturing any definite number, yet I suppose that the enormous number of 400 million must now be far below the mark, and photography still grows better year by year. It seems useless to consider whether the number of stars has any limit, for infinite number, space, and time transcend our powers of comprehension. We must then make a virtue of necessity, and confine our attention to such more limited views as seem within our powers.

A celestial photograph looks at first like a dark sheet of paper splashed with whitewash, but further examination shows that there is some degree of method in the arrangement of the white spots. It may be observed that the stars in many places are arranged in lines and sweeping trains, and chains of stars, arranged in roughly parallel curves, seem to be drawn round some centre. A surface splashed at hazard might present apparent evidence of system in a few instances, but the frequency of the occurrence in the heavens renders the hypothesis of mere chance altogether incredible.

[1] Lord Kelvin has estimated the age of the earth from the rate of increase of temperature underground. But the force of his argument seems to be entirely destroyed by this result.

[2] See W. E. Wilson, NATURE, July 9, 1903; and G. H. Darwin, NATURE, September 24, 1903.

Thus there is order of some sort in the heavens, and, although no reason can be assigned for the observed arrangement in any particular case, yet it is possible to obtain general ideas as to the succession of events in stellar evolution.

Besides the stars there are numerous streaks, wisps, and agglomerations of nebulosity, the light of which we know to emanate from gas. Spots of intenser light are observed in less brilliant regions; clusters of stars are sometimes imbedded in nebulosity, while in other cases each individual star of a cluster stands out clear by itself. These and other observations force on us the conviction that the wispy clouds represent the earliest stage of development, the more condensed nebulæ a later stage, and the stars themselves the last stage. This view is in agreement with the nebular hypothesis of Laplace, and we may fairly conjecture that the chains and lines of stars represent pre-existing streaks of nebulosity.

As a star cools it must change, and the changes which it undergoes constitute its life-history, hence the history of a star presents an analogy with the life of an individual animal. Now, the object which I have had in view has been to trace types or species in the physical world through their transformations into other types. Accordingly it falls somewhat outside the scope of this address to consider the constitution and history of an individual star, interesting although those questions are. I may, however, mention that the constitution of gaseous stars was first discussed from the theoretical side by Lane, and subsequently more completely by Ritter. On the observational side the spectroscope has proved to be a powerful instrument in analysing the constitutions of the stars, and in assigning to them their respective stages of development.

If we are correct in believing that stars are condensations of matter originally more widely spread, a certain space surrounding each star must have been cleared of nebulosity in the course of its formation. Much thought has been devoted to the determination of the distribution of the stars in space, and although the results are lacking in precision, yet it has been found possible to arrive at a rough determination of the average distance from star to star. It has been concluded, from investigations into which I cannot enter, that if we draw a sphere round the sun with a radius of twenty million millions of miles,[1] it will contain no other star; if the radius were twice as great the sphere might perhaps contain one other star; a sphere with a radius of sixty million millions of miles will contain about four stars. This serves to give some idea of the extraordinary sparseness of the average stellar population; but there are probably in the heavens urban and rural districts, as on earth, where the stars may be either more or less crowded. The stars are moving relatively to one another with speeds which are enormous, as estimated by terrestrial standards, but the distances which separate us from them are so immense that it needs refined observation to detect and measure the movements.

Change is obviously in progress everywhere, as well in each individual nebula and star as in the positions of these bodies relatively to one another. But we are unable even to form conjectures as to the tendency of the evolution which is going on. This being so, we cannot expect, by considering the distribution of stars and nebulæ, to find many illustrations of the general laws of evolution which I have attempted to explain; accordingly I must confine myself to the few cases where we at least fancy ourselves able to form ideas as to the stages by which the present conditions have been reached.

Up to a few years ago there was no evidence that the law of gravitation extended to the stars, and even now there is nothing to prove the transmission of gravity from star to star. But in the neighbourhood of many stars the existence of gravity is now as clearly demonstrated as within the solar system itself. The telescope has disclosed the double character of a large number of stars, and the relative motions of the pairs of companions have been observed with the same assiduity as that of the planets. When the relative orbit of a pair of binary or double stars is examined, it is found that the motion conforms exactly to those laws of Kepler which prove that the planets circle

[1] This is the distance at which the earth's distance from the sun would appear to be 1″.

round the sun under the action of solar gravitation. The success of the hypothesis of stellar gravitation has been so complete that astronomers have not hesitated to explain the anomalous motion of a seemingly single star by the existence of a dark companion; and it is interesting to know that the more powerful telescopes of recent times have disclosed, in at least two cases, a faintly luminous companion in the position which had been assigned to it by theory.

By an extension of the same argument, certain variations in the spectra of a considerable number of stars have been pronounced to prove them each to be really double, although in general the pair may be so distant that they will probably always remain single to our sight. Lastly, the variability in the light of other apparently single stars has proved them to be really double. A pair of stars may partially or wholly cover one another as they revolve in their orbit, and the light of the seemingly single star will then be eclipsed, just as a lighthouse winks when the light is periodically hidden by a revolving shutter. Exact measurements of the character of the variability in the light have rendered it possible not only to determine the nature of the orbit described, but even to discover the figures and densities of the two components which are fused together by the enormous distance of our point of view. This is a branch of astronomy to which much careful observation and skilful analysis has been devoted; and I am glad to mention that Alexander Roberts, one of the most eminent of the astronomers who have considered the nature of variable stars, is a resident in South Africa.

I must not, however, allow you to suppose that the theory of eclipses will serve to explain the variability of all stars, for there are undoubtedly others the periodicity of which must be explained by something in their internal constitution.

The periods of double stars are extremely various, and naturally those of short period have been the first noted; in times to come others with longer and longer periods will certainly be discovered. A leading characteristic of all these double stars is that the two companions do not differ enormously in mass from one another. In this respect these systems present a strongly marked contrast with that of the sun, attended as it is by relatively insignificant planets.

In the earlier part of my address I showed how theory indicates that a rotating fluid body will as it cools separate into two detached masses. Mathematicians have not yet been able to carry their analysis far enough to determine the relative magnitudes of the two parts, but so far as we can see the results point to the birth of a satellite the mass of which is a considerable fraction of that of its parent. Accordingly See (who devotes his attention largely to the astronomy of double stars), Roberts, and others consider that what they have observed in the heavens is in agreement with the indications of theory. It thus appears that there is reason to hold that double stars have been generated by the division of primitive and more diffused single stars.

But if this theory is correct we should expect the orbit of a double star to be approximately circular; yet this is so far from being the case that the eccentricity of the orbits of many double stars exceeds by far any of the eccentricities in the solar system. Now See has pointed out that when two bodies of not very unequal masses revolve round one another in close proximity the conditions are such as to make tidal friction as efficient as possible in transforming the orbit. Hence we seem to see in tidal friction a cause which may have sufficed not only to separate the two component stars from one another, but also to render the orbit eccentric.

I have thought it best to deal very briefly with stellar astronomy, in spite of the importance of the subject, because the direction of the changes in progress is in general too vague to admit of the formation of profitable theories.

We have seen that it is possible to trace the solar system back to a primitive nebula with some degree of confidence, and that there is reason to believe that the stars in general have originated in the same manner. But such primitive nebulæ stand in as much need of explanation as their stellar offspring. Thus, even if we grant the exact truth of these theories, the advance towards an explanation of the universe remains miserably slight. Man is but a microscopic being relatively to astronomical space, and he lives on a puny planet circling round a star of inferior rank. Does it not then seem as futile to imagine that he can discover the origin and tendency of the universe as to expect a housefly to instruct us as to the theory of the motions of the planets? And yet, so long as he shall last, he will pursue his search, and will no doubt discover many wonderful things which are still hidden. We may indeed be amazed at all that man has been able to find out, but the immeasurable magnitude of the undiscovered will throughout all time remain to humble his pride. Our children's children will still be gazing and marvelling at the starry heavens, but the riddle will never be read.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY REAR-ADMIRAL SIR W. J. L. WHARTON, K.C.B., F.R.S., PRESIDENT OF THE SECTION.

IT is sometimes denied to Geography that she has any right to consider herself as a science, the objection being apparently founded on the view that it is a subject that can be learnt by heart, but not studied on any systematic line or reduced to principles which enable advance to be made, as in the more exact sciences, by continual investigation by means of laws discovered in the course of such investigation. This, it appears to me, is a misapprehension due to an incomplete recognition of what Science is, and of what Geography is.

Science is, in its simplest interpretation, "knowledge," such knowledge as comes from an intimate acquaintance with and study of any subject duly coordinated and arranged. The subjects which the advancing education and civilisation of the world have caused to be minutely studied are very many, and as knowledge has increased specialisation has become a necessity, until the list of sciences is very long.

Science may be broadly divided into several categories.

Pure or Exact Science, such as Mathematics; Natural or Physical Science, which rests on observations of Nature; Moral Science, which treats of all mental phenomena.

Some Sciences are of ancient foundation, some have arisen from new inquiries and needs of man, or from fissure in subjects too wide for convenient treatment as one.

Many of them are capable of exact definition, and their boundaries and limits can be well marked.

To others no very distinct limitations can be assigned. From their nature they overlap and are overlapped by other subjects, and it is impracticable to confine them by a strict line.

Geography is one of the latter.

Geography is one of the most ancient subjects studied with the view of coordinating facts. A desire for exact knowledge of, first, the bearings and distances of one place from another for the purposes of intercommunication must have arisen as soon as men became collected into groups whose growing civilisation and needs required travel to obtain what could not be obtained in the community. This was the earliest form of Geography, and it is an aspect which still remains, and to some is, in the modern shape of maps, the principal, if not the sole, end of Geography.

From the earliest times, however, geographical information included other than topographical data.

It was soon found that for the traveller and statesman, whether in peace or war, more was wanted to enable Geography to supply requirements.

The nature of a country, the supply of food and water, the characters of the rivers, the manners and customs of the inhabitants, their language and affinities, the climate, and other matters, were all of much moment, and Geography dealt with them all, being, as its name denotes, in the broadest sense a "description of the earth."

After the first crude guesses of relative positions,

founded on times occupied on journeys, other knowledge was enlisted in the cause.

Astronomy was soon recognised as the only means by which to ascertain the distances of places far apart and separated by seas, but for many centuries this could only be applied to latitude. Still the scientific geographer had to study and use the astronomical and geodetic methods known.

As knowledge increased, the subjects became too wide to be strictly considered as one study, and many have become the objects of special research under different titles.

Geodesy deals with the precise form of the earth and its dimensions.

Geology studies the nature of the materials forming the earth's crust, and the changes in it in past ages.

Ethnology and *Anthropology* treat of the different races of mankind.

The study of *Economics* takes note of the conditions of communities and nations, their laws and systems of government.

Botany and *Zoology* now concern themselves with the details of vegetable and animal life.

Archæology investigates the remains of past civilisations which cover the earth.

Meteorology strives to unravel and reduce to law the complicated conditions of the atmosphere, its continual movements, and the results which have such varying effect on our daily life.

Oceanography, the study of the phenomena of the sea as distinct from the dry land, is still regarded as an integral part of Geography, but is rapidly becoming a subject by itself.

Of all these subjects Geography may be considered to be the parent; and though the family be large and has gone off on many separate lines, it is necessary when taking a large and comprehensive view of the united results of knowledge thus gained, especially from the point of view of Distribution, to return to that parent and consider them on a general or geographical basis.

I cannot pretend to define Geographical Science in a clearer or shorter form than that in which it has been already put by General Sir Richard Strachey, and I will quote his words:—

"To investigate and delineate the various features of the earth, to study the distribution of land and sea, and their effects upon climate, the configuration and relief of the surface, positions on the globe, and so forth, facts which determine the existent conditions of various parts of the earth, or which indicate former conditions, and to ascertain the relations that exist between those features and all that is observed on the earth."

Strabo, in the opening words of his introduction to his great Geography, puts it thus:—

"If the scientific investigation of any subject be the proper avocation of the philosopher, Geography, the science of which we propose to treat, is certainly entitled to a high place. In addition to its vast importance in regard to social life and the art of government, Geography unfolds to us the celestial phenomena, acquaints us with the occupants of the land and ocean, and the vegetation, fruits, and peculiarities of the various quarters of the earth."

This was written when Geography included all natural science, and before it gave birth to so many separate subjects; but it sets forth so admirably the aims which the geographer still pursues that it is worthy of remembrance.

It is not advocated, nor is it in any way necessary, that all should study Geography in the extended sense thus indicated; but it cannot be too strongly pointed out that an educated man—and education is now essential to the successful conduct of affairs—must have a considerable knowledge of the elementary facts of Geography.

These elementary facts are, it is true, of the nature of a lesson, and must be learnt, so to speak, by heart by the aid of maps and books; but this is nothing more than making use of the labours of others without which no advance is possible in any subject, and is common to all studies.

We must, in fact, distinguish between the science of Geography, which consists in ascertaining and coordinating new facts, and putting them into a shape for the use of others, which is the work of comparatively few; and the practical Geography which consists of making use of that work, and, as in many other branches of science, is within the reach of all who choose to devote time to it.

It is the object and business of the British Association to try to interest their fellow-countrymen in all branches of knowledge, to gain if possible more workers in science, but at any rate to induce all educated persons to take advantage of the solid work done by others towards the elucidation of the details of the glorious Nature which surrounds us on all sides, and in so many forms, and without which ignorance and superstition, those primary bars to the advancement of mankind, can never be banished.

It is impossible to have a clear comprehension of history, whether past or current, without calling in the aid of Geography; but unfortunately much history has been written and taught without such aid.

To read the daily paper requires either geographical knowledge or constant reference to maps; and if readers would only make a practice of such reference on every occasion when they are at fault, they would soon find themselves acquiring knowledge of the greatest use to them in the easiest and most interesting manner, and with the smallest expenditure of time.

The mistakes made even by those responsible for the conduct of public affairs, by reason of the want of this essential but elementary knowledge, are innumerable, and to this day there are many who consider themselves highly educated and capable men who cannot even rightly understand a map.

As I have before indicated, good maps are the foundation of all sound geographical knowledge, and these maps must be founded on good surveys.

Now a good survey is a comparatively modern operation, and the parts of the world that have been subjected to it are small indeed.

It is true that we now have general maps of the larger parts of the world, which more or less convey a fair representation of the configuration of land and sea when large areas are considered, but details are sadly lacking almost everywhere.

It is not astonishing, for to make the necessary surveys requires an enormous expenditure of both time and money, and the latter is hard to get until the necessity for its expenditure is patent to the smallest intelligence. Thus many countries long settled and in a high state of civilisation are still without any organised system of survey or maps, and even in the United Kingdom it is only from the year 1784 that a proper survey was established of the British Isles, though no maps were published from it until 1801; and it has proceeded so slowly that it has only recently been in one sense completed, while its revision, badly wanted on account of changes, is still in active prosecution, and must be continued *ad infinitum*.

Such indifference is, however, giving way to experience of the results of absence of proper maps, and all who wish well to the progress of South Africa must be pleased at finding that their provision has been taken in hand on such an admirably scientific basis as is provided by the Trigonometrical Survey, now far advanced, and the successful progress of which is, I believe, greatly due to the inexhaustible energy of my friend Sir David Gill, who seems to find time to promote and aid all branches of knowledge, and that steps are now being taken to prosecute the detailed topographical survey and provide good maps.

To many people one map is as good as another. They do not pause to consider on what it is based, or what degree of accuracy it probably possesses, but so long as there is a map they are satisfied.

A vast number of existing maps are compiled from the roughest materials: in partly occupied countries, from drawings of small areas placed together as can best be done, by means of places here and there, the relative positions of which are fairly known by distances along roads, with perhaps in some cases angles and astronomical positions; in less civilised parts by routes of travellers laid down by estimation of the distance traversed and direction of march, checked perhaps by a few astronomical observations of more or less value as the traveller possesses or does not possess the necessary skill.

The compilers of such a map have a difficult task. Discrepancies are, of course, multitudinous. Nothing agrees, and one has to accept, reject, and adjust as best he can on his own responsibility and with what knowledge he can procure of the respective trustworthiness of each author.

Happy is he if he has even a few positions in his map which have been properly determined, as between them he is saved from the constantly increasing errors of adding one little area to another, which if carried on indefinitely culminates in great errors.

Of course such maps are of no practical use, save as giving a very general idea of a country, and when required by the administrator or traveller lead to endless mistakes and annoyances.

The feature of our globe which is now, broadly speaking, most accurately laid down is the coast-line. The safety of navigation has caused general marine surveys to be carried on all over the world during the nineteenth century, which have finally determined the position and shape of the boundaries of the sea.

These surveys, executed for the most part by skilled naval officers with proper instrumental outfit, and supplied especially with trustworthy chronometers, and based upon frequent carefully determined astronomical positions, have resulted in this boundary line being delineated with an accuracy, so far as its absolute position is concerned, far in advance of any other main feature in maps.

Here I may perhaps explain to those unversed in these matters why this is so.

The position of any spot on the earth's surface can be ascertained in two ways: either by careful measurement by means of an accurate system of triangles from another spot already fixed, or by independent observations of the heavenly bodies and calculations from them, which give the precise latitude and longitude of the place. The former is suitable for positions inland, but entails much time and labour, and is only adopted when a perfect map is to be made, for which it is the indispensable foundation. The latter can be carried on from a ship, and in most circumstances only from a ship, because of the limitations of the methods of determinating longitudes.

Longitude can now be satisfactorily and rapidly ascertained in two ways: by the electric telegraph or by use of chronometers.

The places served by the electric telegraph are still few, and its use is therefore restricted; but the chronometer has been in working use for more than a hundred years.

This instrument, which is merely a watch of especial construction, will only keep a steady rate when it is undisturbed by irregular shocks or motions.

No means have yet been found for transporting a chronometer on land without upsetting its regularity, and therefore rendering it useless; but on board a ship it can be so suspended and stowed as to prevent its being disturbed by any ordinary movements of or in the ship. The accurate time of any place departed from, ascertained by astronomical observations, can therefore be carried about on board ship for considerable periods, and by comparison with the local time, also determined by sextant observations of the heavenly bodies, at any required spot on the coast, the difference of longitude is at once obtained with very small limits of error when a number of chronometers are employed. These two simple yet marvellous instruments, the sextant and the chronometer, have thus placed in the hands of sailors ready means of fixing with great exactitude and celerity the position of selected points on coasts all over the world; and it will be seen that, while the detail of the line of coast between such fixed positions will depend upon the degree of accuracy of the survey or sketch, the general line cannot get far out, as it is constantly checked at the selected points.

It is not claiming too much to say that at the present time very few salient points on the coast-lines of the world are as much as two miles in doubt.

It should be a source of great satisfaction to the Briton to know that both these instruments were devised by Englishmen, John Hadley producing the sextant in 1730, in the form still used, on the basis of ideas formulated by Newton fifty years before; and John Harrison the chronometer in 1736. The latter instrument has undergone modifications in detail, but the principle remains the same. It required seventy years before its value was fully recognised and it came into general use.

It is a still further satisfaction to think that it is British naval officers who have made by far the greatest use of them in mapping the coasts of the whole world. Since the time of the great Captain Cook British surveying vessels have been constantly employed in this work, not only in British colonies, but in all parts, aiding and often paving the way for British commerce, and for the men-of-war that protect it.

It is difficult to find coasts of any extent that have not been laid down by British marine surveyors. The whole of Africa has been their work. By far the greater part of America, all the south and east coasts of Asia, Australia, and most of the innumerable islands in all oceans have been fixed and laid down by them. Even in the Mediterranean, until very lately, the charts were mostly founded on British surveys, and the improvements now being carried out by other nations on their own coasts in details required for modern navigation do not materially modify the main shapes and positions formerly determined by the British.

It has been, and is, a great work, and I hope I may be pardoned for dwelling on it with pride as the result of the wise administration of the Admiralty for many years, and of the immediate labours of my predecessors as Hydrographer, and as a very great contribution to geographical knowledge, more especially as I do not think that it is generally realised that this great advance in geographic accuracy is due to marine surveyors.

To give an idea of the comparative accuracy of the chronometer method, I may mention that on taking at hazard eleven places distributed all over the world at great distances from England, the longitudes of which have been recently determined by means of the electric telegraph and elaborate series of observations, I find that the average difference between the chronometer and the telegraph positions is 700 yards. The shapes of the different continents and the positions of islands as at present on our maps and charts will never be altered except in insignificant degree, and the framework is ready for many years' work of land mapping.

It is not to be inferred from what I say that marine surveys are approaching their close. It is far otherwise. The time given to these enormous extents of coasts and seas, and the necessarily small scales on which the surveys have been carried on, have caused them to be very imperfect in all details. Hundreds of rocks and shoals, both stretching from the land and isolated in the sea, have been missed in the course of them, and loss of ships and life on these unknown dangers still continues. With the increase of shipping, increased number of ships of heavy draught, the closeness of navigation due to steam, and the desire to make quick passages, smaller inaccuracies of the charts become yearly of greater importance.

As an illustration of the condition of affairs I may mention that in Hamoaze, the inner harbour of Plymouth, one of the headquarters of the British fleet for more than 300 years, a small but dangerous pinnacle of rock was only discovered five years ago; whilst numerous other dangers of a similar character have been yearly revealed in close surveys of other harbours in the United Kingdom, supposed to be well examined and charted in the last century.

There never was a greater need for close marine surveys of places frequented by ships than now.

It is interesting to look back and see the gradual progress of the delineation of the world and to mark how very recent any approach to accuracy is.

The very earliest maps of any extent of country are unfortunately lost to us. The first man who made a map of which any historical record exists is Anaximander of Miletus, about 600 B.C., but we know nothing of it. A map is mentioned by Herodotus as having been taken in 500 B.C. by Aristagoras of Miletus in the shape of an engraved bronze plate whereon the whole circuit of the earth was engraved, with all its seas and rivers, to influence Cleomenes, King of Sparta, to aid the Ionians against Persia. This was probably the work of Hecatæus, to whom early Geography owed much. His works are also only known to us by quotation; but they are especially interesting as containing an early idea of the limits of Africa, which he

represents as entirely surrounded by the sea—a circumstance apparently either forgotten or disbelieved in later years.

Erotosthenes, 250 B.C., and Hipparchus, 150 B.C., made great advances, and the former made the first attempt to measure the size of the earth by the difference of latitudes between Assouan and Alexandria in Egypt, an attempt which, considering the great imperfection of his means, was remarkably successful, as, assuming that we are right in the length of the stadium he used, he made the circumference of the globe 25,000 geographical miles, whereas it should be 21,600.

He also devised the system of meridians and parallels as we now have them; but the terms "latitude" and "longitude," to denote positions on those circles, were introduced by Ptolemy.

The maps of Ptolemy, the great Alexandrian astronomer and geographer of A.D. 150, are the earliest we possess. He drew, besides a general map of the whole known world from the southern part of the Baltic to the Gulf of Guinea, north and south, and from the Canary Islands to the China Sea, east and west, a series of twenty-six maps of the different parts.

Ptolemy's maps and his method of representing the spherical globe on a flat surface had a great influence on Geography for many years. After his time the Greek civilisation waned, and the general decline of the Roman Empire, followed by its disruption by the invasion of barbarians, closed the course of discovery in all branches of research for centuries. It is not too much to say that for 1300 years no advance was made, and until the commencement of exploration by sea, which accompanied the general revival of learning in the fifteenth century, Ptolemy's maps represented the knowledge of the world.

As might be expected, the further he got from the Mediterranean, the greater were his errors; and his representations of Eastern Asia and North-Western Europe are somewhat grotesque, though quite recognisable in the main.

Of Africa south of the Equator he knows nothing, and his map of it terminates with the border.

This is somewhat remarkable, as I am one of those who firmly believe in the circumnavigation of Africa by the Phœnicians sent by Necho, King of Egypt, in 600 B.C. from the head of the Red Sea. As described by Herodotus, the voyage has all the impress of veracity. My personal faith in Herodotus was much strengthened by finding when I surveyed the Dardanelles in 1872 that his dimensions of that strait were nearer the truth than those of other and later authorities, even down to the time at which I was at work, as well as by other geographical tests I was able to apply. When, therefore, he records that the Phœnicians declared that in their voyage they had the sun on their right hand, and says he does not believe it, he registers an item of information which goes far to prove the story correct. Influenced by Hecatæus, who though surrounding Africa by the sea cut it far short of the Equator, Herodotus could not conceive that the travellers had passed to the south of the sun when it was in the southern tropic.

No historical incident has been more discussed than this voyage, commentators varying much in their opinions of its truth. But we have to-day some new facts. No one who has followed the exploration of the ancient buildings in Rhodesia, and considered the information we possess on the early inhabitants of Southern Arabia, whether we call them Sabæans or Himyarites, can doubt that the former were mainly the work of men coming from Arabia at a very early date, while the period of time necessary to carry out gold-mining operations over the large areas now found to have been exploited must have been very great.

It seems strange that no record of the constant voyages to this El Dorado should remain, but the very natural desire to keep lucrative information to themselves is not an unknown thing amongst traders of the present day, while the conditions of society and the absence of written records of South Arabia would make concealment easy.

The Phœnicians, an allied race, and the great seafaring trading nation of the Mediterranean, succeeded in keeping the majority of their marts secret, and we have incidents recorded showing their determination not to allow others to follow their steps, while to this day we are very doubtful of the limits of their voyages.

It may be considered certain that while we naturally quote Greek historians and geographers as the early authorities for the growth of geographical knowledge, and that the scientific basis for proper maps of large areas was really provided by them, the seafaring nations, Arabians, Phœnicians, and Chinese, knew a very great deal practically of the coasts of various parts of the Old World that were absolutely unknown to the Greeks.

The favourable conditions afforded by those remarkable periodic winds, the monsoons, would in the China Sea, Bay of Bengal, and the Arabian Sea naturally facilitate any attempts at extensive sea voyages, and would lead to such attempts under conditions that in the regions of variable winds would be considered too dangerous and uncertain. The fact that the monsoons in nearly every case blow practically parallel to the coasts in opposite directions is a most important factor in considering early navigation. The direction of the wind itself in such cases roughly guides a vessel without a compass, and the periods of cyclones and unsettled weather between the monsoons would soon be noted and avoided, as they are to this day by the Arabs and Chinese, whose vessels, I have very little doubt, have remained practically the same for thousands of years.

The unknown Greek author of that unique and most interesting document, the "Periplus of the Erythræan Sea," probably of the first century A.D., describes vessels built without nails, the planks of which were bound together by cords, in precisely the same way as many Arab dhows now navigating the Indian Ocean. His personal knowledge of Africa evidently ceased at Cape Guardafui, though he gives information gained from others on the East Coast as far as Zanzibar, which—or, rather, a part on the mainland near—he describes as the limit of trade to the south. We know that Arabs had penetrated further, but no doubt they kept their knowledge to themselves.

These early navigators very probably had charts. When Vasco da Gama first passed along the eastern coast of Africa he found that the Arab dhows had charts. Unfortunately none of them has come down to us, or it would have been interesting to compare them with those of the West Coast used by the Portuguese at the time, and which were of the crudest description.

I claim for sailors of all ages that they would be the first to make practical maps of the shape of the coasts. Their safety and convenience demanded it, while it is a far easier task to compile such a picture of the earth from successive voyages along coasts over the sea, where average distances from known rates of sailing and courses from the sun and stars can be more accurately ascertained, than from long and generally tortuous land journeys in directions governed by natural features, towns, and so forth. A navigator *must* be a bit of an astronomer. A landsman to this day seldom knows one star from another.

It was the sea-charts, or *portolani*, of the Middle Ages that on the revival of learning first gave respectable representations of the shape of the coasts, at a time when the learned monks and others were drawing the most fantastic and absurd pictures which they called maps.

At the same time it must be remembered that in all ages and down to the present day pilots, who within a hundred years were usually carried by all ships, even for sea voyages, jealously keep their knowledge largely in their heads, and look upon good charts as contrivances to destroy their profession, and that such charts or notes as they had they would keep religiously to their fraternity.

The Egyptians were no sailors, but we know that they habitually employed Phœnicians for sea expeditions, while we have the historical record of the Old Testament for their employment by David and Solomon for a like purpose in the Red Sea, and probably far to the south. It is, therefore, almost impossible to doubt that the Phœnicians were also acquainted with the navigation of the Red Sea and east coast of Africa. Such a voyage as that recorded by Herodotus would in these circumstances be far from improbable.

The varying monsoons which had led the Arabians centuries before to get so intimate a knowledge of the east coast as to enable them to find and work the goldfields would be well known to the Phœnicians, and the hardy seamen who braved the tempestuous regions lying between

Cadiz and Great Britain would make little of the difficulties of the African seas.

The limit of easy navigation from and to the Red Sea is Sofala. I do not think that it is too great a use of imagination to suppose that it would be from information received in what is now North Rhodesia that it was learnt that to the westward lay the sea again, and that this led to the attempt to reach it by the south.

Once started from the neighbourhood of Sofala, they would find themselves in that great oceanic stream, the Agulhas Current, which would carry them rapidly to the southern extremity of Africa.

I, as a sailor, can also even conceive that finding themselves in that strong current they would be alarmed and attempt to turn back, and that after struggling in vain against it they would have accepted the inevitable and gone with it, and that without the Agulhas Current no such complete voyage of circumnavigation would have been made.

As Major Rennell in the last century pointed out, once past the Cape of Good Hope, the periodic winds, and over a great part of their journey the currents, would help them up the West African coast; and the general conditions of navigation are favourable the whole way to the Straits of Gibraltar, the ships keeping, as they would do, near the land; but we can well understand that, as recorded, the voyage occupied nearly three years, and that they halted from time to time to sow and reap crops. I should say that it is highly probable that either Simon's Bay or Table Bay was selected as one of these stopping-places.

No reference to this voyage has been found amongst the hieroglyphic records, and, indeed, so far few such records of Necho, whose reign was not for long, are known; but that it was regarded at the time as historical is evident, for Xerxes, a hundred years later, sent an expedition to repeat it in the contrary direction.

This, however, failed, and the unfortunate leader, Sataspes, was impaled on his unsuccessful return.

This attempt shows that the greater difficulty of the circumnavigation from west to east, as compared with that from east to west, was not realised, and points to the concealment of any details of the successful voyage.

Of Hanno's voyage from the Straits of Gibraltar to about Sierra Leone, the date of which is uncertain, but from 500 to 600 B.C., we should know little had not good fortune preserved the record deposited in a Carthaginian temple.

But the well-known secrecy of the Phœnicians in all matters connected with their foreign trade and voyages would explain why so little was known of Necho's voyage, and our present knowledge of the extensive ancient gold workings of Rhodesia shows how much went on in those times of which we are wholly ignorant.

I have dwelt perhaps too long on this subject, but it has to me a great interest; and as it has not, so far as I know, been dealt with by a seaman who is personally well acquainted with the ways of seamen in sailing ships and with the navigation of the coasts in question, I hope I may be excused for putting my views on record.

There are several references in Greek and Latin historians to other circumnavigations, but none of them can be trusted, and apart from Necho's voyage we hear nothing of the east and south coasts of Africa until the arrival of the Portuguese at the end of the fifteenth century. But they found a thriving civilisation along the coast from Sofala northward, Shirazi, Arab, and Indian.

Ruins exist in many places which have not yet been properly investigated, and we are quite unable to say from what date we are to place the earliest foreign settlements, nor how many breaks existed in the continuity of the gold-mining, which apparently was proceeding at or very shortly before the Portuguese visit.

After the recommencement of exploration by sea in the fifteenth century, seamen slowly gathered enough information to draw the lines of the coasts they passed along, and in time—that is, by the middle of the eighteenth century—most lands were shown with approximately their right shapes. But of true accuracy there was none, for the reason I have before mentioned, that there was no exact method of obtaining longitude.

If we look at a general world chart of A.D. 1755—and to get the best of that period we must consult a French chart—we shall find on this small scale that the shape of the continents is fairly representative of the truth. But when we examine details we soon see how crude it all is.

I have compared with their true positions the positions of thirty-one of what may be taken as the fundamental points in the world as given in the larger scaled French charts of 1755, from which the general one is drawn, and I find that on an average they are forty-eight miles in error. The errors vary from 160 miles to two miles. If the delineation of the coast-lines between be considered the inaccuracies are very much greater.

Very shortly after this date more accurate determinations began to be made. The method of lunar distances was perfected and facilitated by tables published in the various astronomical "ephemerides," and seamen and explorers commenced to make use of it. Still the observation required constant practice, and the calculation, unless constantly made, was laborious, and it was used with complete success by the few. The great Captain Cook, who may be looked upon as the father of modern methods of surveying, did much to show the value of this method; but the chronometer came into use shortly after, and the principal advance in exact mapping was made by its aid, as I have already stated.

There is a vast amount yet to be done for Geography. Until we possess publications to which we can turn for full information on all geographical aspects of things on this globe of ours, there is work to be done. Seeing that our present publications are only now beginning to be worthy of being considered trustworthy for the very small amount of knowledge that we already possess, geographical work in all its branches is practically never-ending.

But of exploration pure and simple very little remains to be done. The charm of travelling through and describing an entirely new country which may be practically serviceable to civilised man has been taken from us by our predecessors, though limited regions still remain in Central Asia and South America of which we know little in detail.

I must except the Polar regions, which are in a somewhat special category, as their opening-up affords few attractions to many people. But a knowledge of the past history of our globe—fit study for human thought—can only be gained by study of the portions still under glacial conditions.

What is there round the South Pole—a continent or a group of large islands? What is going on there? What thickness does ice attain? Have these regions always been glaciated; and if not, why not? Can we get any nearer the mystery of magnetism and its constant changes by study at or near the magnetic poles? All these and many other scientific questions can only be solved by general geographical research in these regions, and all interested in such questions have been delighted at the recent attempts to gain more knowledge.

The object of these expeditions was frankly and purely scientific. All hope of remunerative whale or seal fisheries had been dispelled by the visit of the Norwegian whalers in 1892 to the region south of Cape Horn, and the known general condition of the land forbade any expectation of other profitable industries, unless indeed gold and other valuable minerals should be found, which is always possible. Beyond the fact that exploring expeditions of this character keep alive the spirit of enterprise and bring out the finest characteristics of a race—which is a point by no means to be despised—no immediate practical benefit was to be expected.

Progress under the conditions must be slow, but I think that Great Britain may well be satisfied with the information collected in the Antarctic by Captain R. F. Scott and his gallant companions. The unfortunate detention of the *Discovery* by an unfavourable summer prevented the further coastal exploration which was part of the programme, but gave opportunity for further detailed examination of the inland conditions, which was carried out in defiance of the severest atmospheric and topographical difficulties, and with the greatest zeal and intelligence; and it may be doubted whether Science in the end has not

gained more than she lost by the unexpected diversion of energy. The healthy conditions which prevailed throughout are a standing proof both of Captain Scott's eminent capacity as a leader and of the cheery spirit which animated the whole expedition.

The full results of the scientific observations are not yet worked out, and in many cases for a complete appreciation of their bearing they must be compared and correlated with those of the other Antarctic expeditions, but many highly suggestive points have already been revealed.

For the first time Antarctic continental land has been travelled over for long distances, and though the actual area of new discovery looks small on a map of the world, the distances covered can only be described as extraordinary, and far exceeding the most sanguine anticipations.

Few who considered the mountainous coast-line of Victoria Land and its complete glaciation, as reported by Sir James Ross from his distant view, thought that it would prove practicable not only to ascend those mountains, but to reach to heights much surpassing them behind.

The reason that it proved feasible is that, while there are occasional heavy snowstorms, the annual snowfall is small, and the surface, therefore, is generally unencumbered with soft deep snow.

And what did Captain Scott find after his memorable struggle up the glacier through the mountains?

An enormous plateau at an elevation of about 9000 feet, nearly level, smooth, and featureless, over which he travelled directly inland for more than 200 miles, seeing no sign at his furthest point of any termination or alteration in character. So far as could be seen from other journeys, glacial discharge from this great ice-sheet is very small, and practically it appears to be dead. Its accretion by fresh snowfall is insignificant, while on all sides along the flanks of the coastal mountains there are signs of diminution in the mass of ice.

The great ice-barrier east of Ross Island tells the same tale. This magnificent feature presents to the sea a face of perpendicular ice-cliffs varying from 60 to 240 feet in height and 450 sea-miles long. Sir J. Ross mapped its position in 1841, and Captain Scott finds that it has retreated on an average fifteen miles, varying much in different parts.

Should this rate of retreat continue the whole of this ice mass, so far as Captain Scott saw it, will have vanished in 1000 years.

As the motion of the ice mass is also about fifteen miles to the north in the same time, icebergs covering collectively an area of 450 miles by 30 have been discharged from it in sixty years.

Captain Scott travelled over it nearly due south to a point 300 miles from its face, and then saw no sign of its end.

It is bordered on its western side by a mountainous coastline, rising in places to 15,000 feet He found the ice practically flat and wholly unfissured, except at the side, where its northerly motion, found to be about 130 feet in the month, caused shearing and vast crevasses. All that is known of its eastern edge is that it is bordered, where it meets the sea, by land from 2000 to 3000 feet high, suspected by Ross and verified by Captain Scott. This may be an island, or more probably the eastern side of the great fiord or bay now filled by the barrier.

Captain Scott is of opinion that this great ice-sheet is afloat throughout, and I entirely agree with this conclusion. It is unexpected, but everything points to it.

From soundings obtained along the face it undoubtedly has about 600 feet of water under it.

It is difficult to believe that this enormous weight of ice, 450 miles by at least 360, and perhaps very much more, with no fall to help it along by gravity, can have behind it a sufficient force in true land glacier to overcome the stupendous friction and put it in motion if it be resting on the bottom. It is sufficiently astonishing that there is force enough even to overcome the cohesion at the side, which must be very great.

The flat nature of the bottom of the Ross Sea and the analogies of many geographical details in other parts of the world make it most probable that the water under the whole barrier is deep.

A point on which I have seen no comment is the difference in the appearance of the slopes of Mount Terror. Captain Scott found the bare land showing over large areas, but during the two summers of Ross's visit it was wholly snow-clad. Sir Joseph Hooker, the sole survivor of Ross's expedition, when questioned had no doubt on the subject, and produced many sketches in support.

This may be due to temporary causes, but all the information collected by the expedition points without doubt to steadily diminishing glaciation in recent times. We have, therefore, this interesting fact, that both in Arctic and Antarctic regions, as indeed all over the world, ice conditions are simultaneously ameliorating, and theories of alternate northern and southern maximum glaciations seem so far disproved.

But this does not mean that climatic conditions in the Antarctic are now less severe—probably the contrary. It has been pointed out by many that land glaciation may arise from varied primary causes, but one obvious necessity is that the snowfall should exceed melting and evaporation. It need not be heavy; but if it is, it may produce glaciation under somewhat unexpected conditions. This would entail a vapour-laden air more or less continuously impinging upon the land at a temperature which will enable it when cooled, either by passing over chilled land or when raised to higher regions by the interposition of mountains, to give up its moisture freely. This condition is not fulfilled when the air as it arrives from the sea is already at a very low temperature.

It was my fortune to spend two long seasons in the Straits of Magellan, and I was daily more impressed by what I saw.

There you have a mountainous ridge of no great height—very few peaks rising more than 4000 feet—opposed to the almost continuous westerly winds pouring in from the Pacific at a very moderate temperature and charged with much moisture.

The result is that in the latitude of Yorkshire every mountain mass over 3000 feet high is covered with eternal snow, and sends glaciers down to the sea.

I was convinced by what was going on under my eyes that it only required an upheaval of the land of 2000 feet or so to cover the whole of Patagonia with ice. But then the climate would still not be very severe. The temperature of the wind from the sea would be the same, and such part of it as blew along the channels and on the lower land would moderate the cold caused by the ice-covered slopes.

The shores of the whole of Western Southern Patagonia, deeply indented with long and deep fiords, indicate, according to all received views of the origin of such formations, that the land was formerly higher, while signs of glaciation are everywhere present.

The results of geographical research show us that in many parts of the world climate must have greatly changed in comparatively recent times.

In the now arid regions of Northern Africa, Central North America, and in parts of Asia there is ample evidence that the climate was in times past more humid. In a remarkable paper on the causes of changes of climate, contributed by Mr. F. W. Harmer to the Geological Society in 1901, and which has not obtained the notice it deserves, it is pointed out how changes in the distribution of the prevalent winds would vastly alter climatic conditions. Like everything else in Nature, and especially in the department of meteorology, these questions are exceedingly complex, and similar results may be brought about in different ways, but there can be no doubt that the climate of South Africa would be greatly modified, and more rainfall would occur, if only the cyclonic storms which now chase each other to the eastward in the ocean south of the Cape of Good Hope could be prevailed upon to pursue a slightly more northerly line, and many obstacles to the agricultural prospects of South Africa now existing would be removed. This is, however, beyond the powers of man to effect; but, as I have just said, there are other ways of attaining the object, and it is earnestly to be hoped that the attention now being paid to afforestation may result in vigorous efforts to bring about by this means the improvement in humidity so much required in many parts of the country.

The other recent event in geographical exploration is the result of the expedition to Lhasa. It was an unexpected solution of this long-desired knowledge that it should come from political necessities and by means of a Government mission. The many ardent travellers who have dreamed of one day making their way in by stealth have thus been disappointed, but our knowledge is now fuller than could otherwise have been gathered.

The most important fact is the revelation of the fertility of a large part of Southern Tibet. Much has been added to topographical knowledge, but the route maps of the secret Indian native surveyors already had given us a rough knowledge of the country on the road to Lhasa. It was not, however, realised how great was the difference between the aridity of the vast regions of the north, known to us from the travels of men of various nationalities, and the better-watered area in the south, though from the great height of the plateau—some 12,000 feet—the climate is very severe. The upper course of the Brahmaputra has been traced by Captain Ryder, but, unfortunately, a political veto was placed on the project to solve the interesting problem of how this great river finds its way to the Indian plains, and this still remains for the future to unravel.

Of the ocean, which has been my own particular study for many years, and on which alone I feel any special qualification to speak, I have said but little, for the reason that when presiding over this Section on a former occasion I took it for my theme, but there are a few points regarding it which I should like to bring to your notice.

It is of the ocean, more than of any other physical feature of our globe, that our knowledge has increased of late years. Forty years ago we were profoundly ignorant even of its depth, with the exception of a few lines of soundings then recently taken for the first submarine telegraph cables, and consequently we knew nothing of its real vast bulk. As to the life in it, and the laws which govern the distribution of such life, we were similarly ignorant, as of many other details.

The *Challenger* expedition changed all this, and gave an impetus to oceanographic research which has in the hands of all nations borne much fruit.

Soundings have been obtained over all parts of the seas, even in the two polar seas; and though much remains to be done, we can now form a very close approximation to the amount of water on our earth, whilst the term "unfathomable ocean" has been shown to have been based on an entire misconception. Biological research has also revealed a whole world of living forms at all depths of the existence of which nothing was known before.

In my former Address, eleven years ago, I gave many details about the sea, of which I will only repeat one—which is a fact that everyone should know—and that is, that the bulk of the ocean is about fourteen times as great as that of the dry land above water, and that if the whole of that land were thrown into the Atlantic Ocean it would only fill one-third of it.

Eleven years ago the greatest depth known was 4700 fathoms, or 28,000 feet. We have since found several places in the Pacific where the depth is nearly 5170 fathoms, or 31,000 feet, or somewhat higher than Mount Everest, which has been lately definitely shown to be the culminating point of the Himalayas. These very deep parts of the ocean are invariably near land, and are apparently in the shape of troughs, and are probably due to the original crumpling of the earth's surface under slow contraction.

The enormous area of the sea has a great effect upon climate, but not so much in the direct way formerly believed. While a mass of warm or cold water off a coast must to some extent modify temperature, a greater direct cause is the winds, which, however, are in many parts the effect of the distribution of warm and cold water in the ocean perhaps thousands of miles away. Take the United Kingdom, notoriously warm and damp for its position in latitude. This is due mainly to the prevalence of westerly winds. These winds, again, are part of cyclonic systems principally engendered off the coasts of Eastern North America and Newfoundland, where hot and cold sea-currents, impinging on one another, give rise to great variations of temperature and movements of the atmosphere which start cyclonic systems travelling eastwards.

The centre of the majority of these systems passes north of Great Britain. Hence the warm and damp parts of them strike the country with westerly winds, which have also pushed the warm water left by the dying-out current of the Gulf Stream off Newfoundland across the Atlantic, and raises the temperature of the sea off Britain.

When the cyclonic systems pass south of England, as they occasionally do, cold north-east and north winds are the result, chilling the country despite the warm water surrounding the islands.

It only requires a rearrangement of the direction of the main Atlantic currents wholly to change the climate of Western Europe. Such an arrangement would be effected by the submergence of the Isthmus of Panama and adjacent country, allowing the Equatorial Current to pass into the Pacific. The gale factory of the Western Atlantic would then be greatly reduced.

The area south of the Cape of Good Hope is another birthplace of great cyclonic systems, the warm Agulhas Current meeting colder water moving up from the Polar regions; but in the Southern Ocean the conditions of the distribution of land are different, and these systems sweep round and round the world, only catching and affecting the south part of Tasmania, New Zealand, and Patagonia.

In 1894 I spoke of the movements of the lower strata of water in the sea as a subject on which we were only beginning to get a little light. Since that year we have learnt a little more. It is a common idea that at the bottom of the sea all is still; but this is a mistake, even for the deepest parts, for the tidal influence reaches to the bottom and keeps every particle in motion, though such motion is quiet and slow.

Near the shore, however, though still in deep water, the movement may be considerably increased. Cases have occurred in late years where submarine cables have broken several hundred fathoms deep, and when picked up for repair it has been found that the iron wire covering has been literally rubbed away as by a file. This can only be the result of an undercurrent along the bottom moving the cable to and fro. Such a current might be caused by a submarine spring, for there is no doubt that much fresh water finds its way into the ocean in this fashion, but it is more probably generally an effect of acceleration of the tidal movement due to the rising slope of the continent.

In connection with this, further facts have come to light in the course of recent marine surveys.

Many isolated shoal spots in the great oceans have figured in our charts, the results of reports by passing sailors who have said they have seen breakers in fine weather.

Such places are the terror of seamen, and it is part of the duty of surveying ships to verify or disprove them. Very much has been done in the last eighteen years, with the result that the majority of them have, as dangers, disappeared. In many cases, however, a bank has been found, deep in the ordinary acceptation of the word, but must less deep than the surrounding sea—solitary ridges, in fact, rising from the ocean floor. Frequently, in examining these banks in search of shoaler spots, breakers have been reported and recognised as such on board the surveying ship from a distance, but on approach they have proved to be small overcurls caused by tide ripplings, and the depth of water has proved to be several hundred fathoms. These ripplings are clearly caused by the small tidal motion in the deep water, generally in these cases of more than 2000 fathoms, meeting the slope of the submerged mountain range, being concentrated and accelerated until the water finally flows up the top of the slope as a definite current, and taking the line of least resistance, that to the surface, makes itself visible in the shape which we are accustomed to associate with comparatively shallow water.

These cases form remarkable instances of the manner in which extensive motion of water may arise from very small beginnings.

An observation I was anxious to make in 1894 has been successfully carried out since. This was to ascertain whether there was any permanent undercurrent in the Straits of Bab-el-Mandeb due to more water being forced through the strait on the surface by the persistent S.E. wind of winter than could be evaporated in the closed Red Sea.

Such return undercurrents have in somewhat similar circumstances been shown to exist in the Dardanelles, Strait of Gibraltar, and in the Suez Canal.

The observation at Bab-el-Mandeb was difficult. The wind is strong and the disturbance of the sea is considerable, while the water is 120 fathoms or 700 feet deep. But a surveying vessel maintained herself at anchor there during four days, and, by the aid of an ingenious apparatus sent from England for the purpose, clearly proved the existence of a current of 1½ knot flowing steadily at depths below 70 fathoms out of the Red Sea, whilst in the upper strata there was a similar current flowing in. In such ways is interchange of water provided for by Nature in places where tidal action does not suffice.

In what I fear is a very discursive Address I have not mentioned the interior of Africa. In the first place, it is a subject of itself; and as we shall have, I hope, many papers on African subjects I have thought it better to deal mainly with generalities.

Still I cannot refrain from a few words to express the astonishment I always feel when I hear people complain that Africa goes slow. When I look at what has been effected in my own lifetime, it appears to me that, on the contrary, it has been rushed. The maps I learnt from as a boy showed the whole interior as a blank. There are now no parts that are not more or less known. The great lakes have all been revealed; the great rivers have all been traced; Europeans are now firmly fixed with decent governments in parts formerly a prey to tribal wars and the atrocities of the inland slave traffic. Railways are running over regions unknown forty years ago, and one of the most astonishing things to me is that I should be able to hope now to visit in comfort and luxury the great Victoria Falls which my old friend Sir John Kirk—whom I left the other day hale and hearty—was, with the exception of Livingstone, the first white man to see, after a long and laborious journey in his company in 1860.

I could not help being amused as well as interested at seeing a short time ago a proclamation by the Government of Northern Rhodesia, dated not far from Lake Bangweolo, calling on all concerned to observe neutrality during the present war between Russia and Japan. I think that if anyone had prophesied to Livingstone, as he lay in 1873 lonely and dying by the shores of that newly discovered lake, that such an edict would be issued in thirty years he would have expressed a doubt as to its fulfilment.

To Southern Africa Nature has denied two of the features that facilitate rapid progress—good harbours and sufficient rainfall—but the energy of man has done wonders to provide the former where possible, and will doubtless do more; whilst I believe that the lack of the latter will also be overcome in the same way. The coordinated—or, in other words, the scientific—observations made in many other countries have pointed out a possible solution. On the other hand, the height of the inland plateaux makes it possible for the white man to live and work in latitudes which would under other conditions be tropical.

South Africa must have a great future before it; and while some present circumstances may delay development of its natural advantages, I am inclined to think that in the long run prosperity may be more solid and material for being reached in the face of difficulties, as has so often occurred in the history of the world.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 21.—M. Bouquet de la Grye in the chair.—On the laws of sliding friction: Paul **Painlevé**. A discussion of a problem suggested by M. de Sparre in a recent paper, and of the conditions necessary for a solution without ambiguity.—The cause of the presence of abnormal quantities of starch in bruised apples: G. **Warcollier**. It is shown that tannin from galls prevents all action of amylase on starch, and it is supposed that the accumulation of starch in bruised apples is due to a similar action.

CALCUTTA.

Asiatic Society of Bengal, August 2.—Additions to the collection of Oriental snakes in the Indian Museum, part iii.: N. **Annandale**. Four new species and a new genus are described, two of the former coming from the Malay Archipelago, one from N.E. India, and one from Gilgit. Notes on other species from different parts of the Oriental region are given. This paper completes the series for the present, the collection now being worked out and arranged.—Sal-ammoniac: a study in primitive chemistry: H. E. **Stapleton**. An attempt to carry back the history of sal-ammoniac through Mohammedan times, and to throw light on the primitive conceptions of nature which led to its introduction as an alchemical drug. Although little used by the Greek school of Alexandria, it was in high repute as one of the alchemical "stones" of the Arabs, and through their agency the substance passed into European alchemy. Authorities are given for the belief that the salt owed its reputation partly to its magical qualities, which were due to its connection with human hair and other animal substances, and partly to its strictly chemical qualities. A suggestion is finally made that the salt was originally introduced into Western Asia through Persia from China.—Alchemical equipment in the eleventh century, A.D.: H. E. **Stapleton** and R. F. **Azo**. This paper is an annotated analysis of an Arabic treatise on alchemy lately discovered in the library of His Highness the Nawab of Rampur. The treatise was written in Baghdad in the year 426 A.H. (1034 A.D.), and though now in a somewhat mutilated state, it affords a welcome addition to our knowledge of alchemical methods and equipment in the eleventh century. Special attention is directed to (1) the great importance attached to weights in chemical operations 700 years before the time of Black and Lavoisier; and (2) the drawings and description of the *Vthāl* (Aludel), which furnish, for the first time from Arabic sources, a clear conception of this instrument.

MARINE ENGINEERING.

Marine Engines and Boilers, their Design and Construction. Based on the work by Dr. G. Bauer. Translated from the second German edition by E. M. and S. Bryan Donkin. Edited by Leslie S. Robertson. Pp. xxviii+744. (London: Crosby Lockwood and Son.) Price 25s. net.

THIS considerable work fills a gap in English engineering literature. For while the related subject of naval architecture has been treated by writers of authority, there is no very good modern book on marine engineering. Dr. Bauer states that it is intended to be a condensed treatise, embodying the theoretical and practical rules used in designing marine engines and boilers. But though thus limited in scope, it treats only of the most modern types and excludes even modern engines and boilers of special types. As might be expected from the engineer-in-chief of the Vulcan Works at Stettin, the machinery of warships and of some of the great German Atlantic liners are very fully illustrated. There is not a great deal of theoretical investigation, but what there is bears very definitely on design, and is sound so far as it goes. Perhaps the most valuable part of the book is the great amount of tabulated information about the proportions of the machinery in good examples of modern practice. There is also a very large collection of those empirical or semi-empirical rules, based on extensive practical experience, on which engineers necessarily so much rely. There is reason to be grateful that an engineer so distinguished as Dr. Bauer, with the care of a great factory on his shoulders, should have found time to produce such a systematic treatise, and that he has been able to obtain the aid of some of his principal technical assistants in dealing with parts of the subject.

The book has been excellently and competently translated, and the translators have undertaken the necessary, but very laborious, task of converting the numerical statements of formulæ from the metric to English measures. However bad our English system of measures may be, English engineers can only think and work in English measures, and the translation would have lost very much of its usefulness if the conversion had not been made. Mr. Leslie S. Robertson, who has edited the volume, has had practical experience in this branch of engineering, and has already published valuable works relating to it. His name is a guarantee that the adaptation of the work for English readers has been, from the technical point of view, thoroughly well done.

The general arrangement of the book is convenient. Part i., which occupies four-tenths of the volume, deals with the main engines. First, indicator diagrams are discussed, and the application of theoretical diagrams in settling cylinder proportions. The well known method of constructing theoretical diagrams from a diagram of the volumes occupied by the steam is given, and an example worked out. The remark is made that "the diagrams so obtained show the characteristics of actual diagrams, but their mean pressures are naturally much higher than they would be in actual practice." That is not our experience. If the data are rightly used, there is a fairly close approximation between the theoretical and actual mean pressures. It is a case in which the precise law of expansion assumed does not very much affect the result. There is one other small point in this chapter. The ratio of an actual to a theoretical diagram is called an "efficiency" (p. 17). This leads to the awkward statement on p. 35 that "the efficiency of triple expansion engines is less than that of single cylinder engines." If the more usual term "diagram factor" had been used instead of efficiency the statement would be less misleading.

Next there is a very short section dealing with some thermal circumstances affecting the utilisation of steam. This is too brief to be satisfactory, even from the point of view of engine design. For instance, the loss due to cylinder condensation is explained by saying that "heat is withdrawn from the steam at high pressure and restored to it at a lower pressure" (p. 37). The essential point that the heat is chiefly restored during exhaust is not mentioned. So the economy of multiple expansion engines is traced to reduction of temperature range. But the re-evaporation during exhaust from one cylinder increases the work in the next. In other respects also the explanation is deficient. However, the thermodynamics of steam engines is fully given in other treatises. An important section follows, in which the stroke, speed, and turning moment are discussed. The theory of torsional vibrations is given, and practical methods of determining the critical speed at which liability to strong torsional vibrations occurs. In connection with this there is a brief but clear and practical treatment of the problem of balancing. Then the arrangement of main engines is explained, and there is a long section dealing with the proportions of engine details and including a sufficient account of valve diagrams.

Part ii. deals with pumps. Part iii. discusses shafting, and in connection with this ship resistance, and the proportioning of propellers. German writers are adepts at tabulating coefficients and data, and the tables in this section are excellent. Part iv. is on pipes and connections. Part v. deals with steam boilers, and is chiefly descriptive of modern types. Here again the tabulated data from actual cases is information of the most useful kind, and the rules of the classification societies, which leave the engineer very little discretion, are fully given. The last section gives some account, rather too much condensed, of instruments used in steam engine and boiler trials. To many readers an account of Fottinger's torsion indicator for measuring the effective horse-power of engines by observing the torsion of the screw shaft will be interesting. Hirn first used a torsion dynamometer of this kind. As a diagram of the torsion angle is obtained, the variation of the power transmitted can be determined.

No account is given of the most recent change in marine engineering, namely, the adoption of the steam turbine in place of reciprocating engines. The success of the steam turbine in this field is already so well assured that a revolution in marine engineering is promised. But there are, no doubt, good reasons for the omission. Experience in the use of steam turbines in ships is almost confined to this country, and naturally at present full information as to the results, mechanical and economic, of the use of turbines is only possessed by a few engineers, and is not generally available.

In this country we still rightly pride ourselves on retaining the highest position in shipbuilding and marine engineering. But, if we still do more work of this kind than any other nation, and if our best work is as good as any in the world, yet Dr. Bauer's book should remind us that in science, experience and skill, other nations now run us very close.

THE BIRDS OF ICELAND.

Beitrag zur Kenntnis der Vogelwelt Islands. By B. Hantzsch. Pp. vi + 341; illustrated. (Berlin: Friedländer and Son, 1905.) Price 12 marks.

SINCE Iceland lies on one of the main migration routes, namely, that which starts from Greenland and Iceland itself, and passes by the Færöes to the British Islands, its bird-fauna is naturally of special interest and importance. This is testified by the appearance within a comparatively short period of two works on the subject, namely, Mr. H. N. Slater's "Manual of the Birds of Iceland," published at Edinburgh in 1901, and the present larger and more pretentious volume. In addition to the general fauna, there is special interest attaching to Iceland as the chief European resort in former days of the gare-fowl, or great auk. The history of this lost bird and the literature relating to it the author reserves for a supplemental volume. Despite all that has been done by travellers and collectors, Mr. Hantzsch is of opinion that our knowledge of the bird-fauna of Iceland is still far from complete, much of the interior of the country being difficult of access and still imperfectly explored by collectors. Accordingly he is fain to admit that the last word on the subject still remains to be said.

The volume commences with an historical survey of the growth of our knowledge of Icelandic ornithology, with notices of the chief explorers and workers in this field of research, and a list of the more important memoirs and books treating of the subject. Then comes a detailed account of the author's own journeys in the island for the purpose of collecting specimens and personally observing the birds. This is followed by an interesting description of the main physical features of Iceland and the neighbouring islets, such as Grimsey in the north and the Westman group in the south, this being illustrated with a number of reproductions of photographs of the scenery taken by the author himself. Special lists are given of the birds of Grimsey and the Westman Islands. Changes in the bird-fauna of the whole group of islands, and the general relationships of the fauna form the subjects of two succeeding chapters, a brief note being appended on domesticated species.

This completes the introductory portion of the subject, which occupies ninety-two pages, and the remainder of the text is devoted to the detailed synopsis of the birds. The total number of species, exclusive of the great auk, recorded in the preliminary list as definitely known to occur in Iceland is 120, in addition to which are a few of which the right to a place among the fauna is somewhat uncertain. Perhaps the most striking feature of the descriptive part of the work is the almost painful severity with which new fashions in ornithological nomenclature are followed, such appalling alliterations as *Merula merula merula* and *Gallinago gallinago gallinago* occurring with wearisome frequency. Without reiterating his own private opinion on nomenclature of this nature, which is now pretty well known, the reviewer may point out that when the typical form of a species is alone recorded, it is perfectly superfluous to add the terminal trinomial, *Merula merula* and *Gallinago gallinago* being in such cases apparently all that can possibly be required.

Excellent photographs of the eggs, nests, or breeding-haunts of some of the rarer species serve to enliven the text, and ornithologists will be greatly interested in the two pictures of the eggs and callow young of the great skua in their natural surroundings. The work will doubtless long remain the standard authority on Icelandic birds, at all events for German readers.

R. L.

OUR BOOK SHELF.

Neue Fische und Reptilien aus der böhmischen Kreideformation. By Prof. Dr. Anton Fritsch and Dr. Fr. Bayer. Pp. 34; plates ix. (Prague: Fr. Rivnac, 1905.)

VERTEBRATE fossils are not only rare, but also badly preserved, in the Cretaceous rocks of Bohemia. Palæontologists must therefore admire the enthusiasm of Dr. Anton Fritsch, who continues to devote to the interpretation of difficult fragments so much study as is evidenced by his numerous writings on these remains. In 1878 he published a complete synopsis of the subject as then understood. Now, with the aid of Dr. Franz Bayer in the determination of fishes, he again publishes an up-to-date treatise, including the discoveries of the last quarter of a century. The work is illustrated in Dr. Fritsch's usual style, and a few of the figures are revised drawings of specimens previously described.

Dr. Bayer's chapter on the Cretaceous fishes was originally published in the Bohemian language in 1902, but is now made more readily accessible in German. He describes evidence of several new genera and species, and concludes that in the Bohemian Chalk there are more varied representatives of the higher fishes than have hitherto been found below the Tertiary formations. In view of the fragmentary nature of most of the fossils, it must be

admitted that this conclusion needs confirmation from future discoveries before it can be definitely accepted. The specimens on which the new genera Coryphænopsis and Bayeria (Fritsch) are founded are certainly remarkable.

Dr. Fritsch's section of the work shows that all the usual groups of Cretaceous Reptilia are represented in the Bohemian rocks. There are undoubted fragments of Plesiosaurs, and there is one interesting brain-cast which the author describes as probably referable to Polyptychodon. Dr. Fritsch, however, overlooks the fact that the skull of Polyptychodon is actually known in England, and is undoubtedly Plesiosaurian or Pliosaurian, not Mosasaurian. Chelonian remains occur, evidently representing turtles related to the small *Chelone Benstedi* from the English Chalk. Some fragments appear to be Mosasaurian, but those described under the new name of *Iserosaurus litoralis* are extremely problematical. Other fragments, ascribed without much reason to Dinosauria, scarcely suffice to justify the new names bestowed on them. Some good new figures of the interesting wing-bones of the small Pterodactyl, *Ornithocheirus hlavaci*, are given, and the volume concludes with a systematic list of species.

A. S. W.

Die Bedeutung des Experimentes für den Unterricht in der Chemie. By Dr. Max Wehner. Pp. 62. (Leipzig and Berlin: B. G. Teubner, 1905.) Price 1.40 marks.

THIS brochure forms part of a "Sammlung naturwissenschaftlich-pädogogischer Abhandlungen," and is very hard reading for an ordinary English chemist. It is divided into two parts, the first of which deals with the importance of experiment for attaining the object of chemical instruction, and the second with the importance of experiment in relation to method in chemical instruction. It is hard reading in the sense that one has to wade through detailed arguments which culminate in conclusions such as "description does not suffice for the instruction of the pupil in chemical processes," and "the development of the laws concerning chemical processes from experimental observations is more effective for chemical teaching than their deduction from quoted examples." The work is, in fact, an example of pure pedagogical exercitation, and it may be recommended with confidence only to those who have a liking for that kind of literature.

A. S.

Monographie des Cynipides d'Europe et d'Algérie. By l'Abbé J. J. Kieffer. Tome second. 2me. fascicule. Pp. 289–748; plates ix–xxi. (Paris: A. Hermann.) Price 18s.

THIS is the conclusion of vol. vii. *bis* of André's great series of monographs, "Spécies des Hymenoptères," and completes the Cynipides, or gall flies. The previous portions have already been noticed in NATURE (vol. lxvii. pp. 124–5, December 11, 1902, and vol lxviii. p. 221, July 9, 1903), and the part now published completes the Cynipides, 5e tribu, Figitinæ; and also includes the Evaniides (divided into two tribes, Evaniinæ and Gasteruptioninæ), the Stephanides, Trigonalides, Agriotypides, general supplements, a "Catalogue méthodique et synonymique," extending from pp. 653 to 741 (double columns), and general indices.

The plan of the work is uniform throughout, and as the previous portions have already been discussed at considerable length, an extended notice is here unnecessary.

W. F. K.

The Gum-Bichromate Process. By J. Cruwys Richards. Pp. 119. (London: Iliffe and Sons, Ltd., n.d.) Price 2s. 6d. net.

THIS process of photographic printing is about fifty years old, but it is only during the last ten years or so that it has been adopted for practical purposes. When first introduced it was deliberately rejected, because it was not equal to the then known processes in reproducing the detail of the negative; latterly it has been taken up and very much appreciated by some of those who desire to be able to alter or "control" their photographic printing, and so obtain results that, while they can lay no claim to mechanical accuracy, more nearly please the æsthetic taste of the worker. At the present time there are more methods of photographic printing than there were a generation ago that are excellently adapted for the purposes of photography pure and simple; therefore the gum-bichromate process is still more than it was then a process for the specialist in the direction named. The author of this volume is well known as a successful worker of the method. He gives his own formulæ, and states clearly the practical details that he prefers to follow, but he also describes the methods of others. He is a warm advocate of "multiple printing"; that is, after coating the paper, exposing, developing with warm water aided with a brush or by other mechanical means, coating, exposing, and developing a second or even a third or more times, so gradually building up the picture with the maximum opportunity of "control." It will be obvious that every possibility of improvement in the hands of the skilful is a probability of error in the hands of the artistically ignorant, and that the process does not claim attention from a photographic point of view at all, but as enabling an artist to express his ideas with less trouble and perhaps with more accurate drawing than if he worked wholly by hand. The volume includes several reproductions of the author's works, some of them showing the print in its various stages of evolution.

LETTERS TO THE EDITOR.

Recent Changes in Vesuvius.

I BEG to enclose a somewhat free translation of a letter I have recently received from Prof. G. Mercalli, of Naples, concerning certain changes which have taken place in Vesuvius this year. During a visit to the mountain on August 14–16, I was able to approach quite near to the sources of the lava streams described by him, and also to examine the remarkable tunnels formed at certain places by the cooled surface of lava streams which had subsequently diminished in volume, or had even "run dry."

During the week preceding my visit, many incandescent bombs of pasty rock had been ejected from the crater at the summit, mostly in the direction of the side facing Pompeii, and these successively rolling down the ash-slope presented a beautiful spectacle at times. The lava streams proper often presented that curious double appearance, due to the fact that the colder and darker scoriæ, floating down the stream, keep to the more swiftly-moving current in mid-stream, and avoid the sides.

Yesternight (August 20) but one of the lava streams referred to by Prof. Mercalli was visible from Naples, the other having apparently ceased.

The explosions of Stromboli are occurring at intervals of about $3\frac{1}{2}$ minutes.

R. T. GÜNTHER.

R.M.S. *Oroya*, off Stromboli, August 21.

Lava Stream of May 27, 1905.

IN the months of April and May of this year Vesuvius began to show an increased activity, and in the crater, which was about 80 metres in depth, a small cone began to form; it increased rapidly, and by the middle of May had risen to a height of about 15 metres above the level of the enclosing crater.

From May 25 to May 27 violent explosions occurred, which were heard in all the villages on the mountain-side,

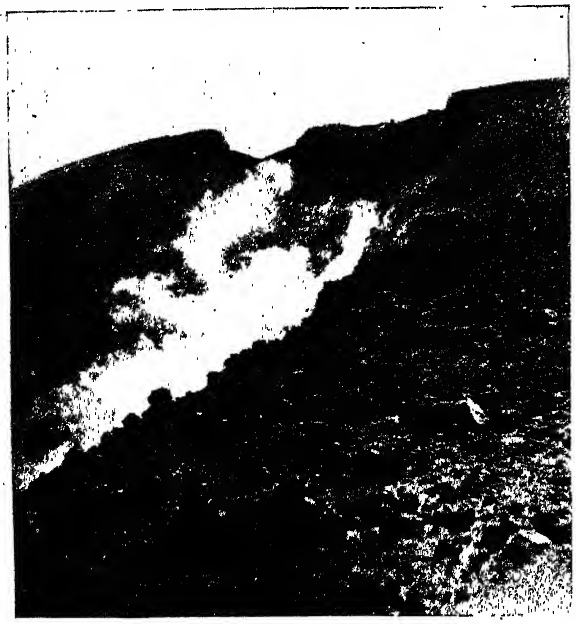

FIG. 1.—Source of lava stream of August 26, 1903. From a photograph by Prof. G. Mercalli, taken April 15, 1904.

and were accompanied by the ejection of much red-hot and liquid matter. These explosions ceased almost suddenly on the evening of May 27, and at about 6.45, a small lateral outlet, "A," burst through the north-west flank of the great cone at a height of about 1245 metres, and at the point where a seam in the mountain-side showed where the traces of the last eruption of August 26, 1903, still lingered.

A few hours after the first, a second outlet was formed, then a third, "B," both lower down, at an altitude of

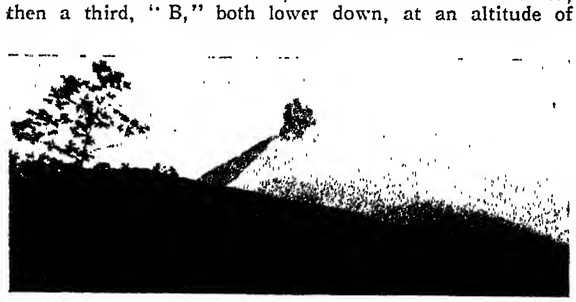

FIG. 2.—Vesuvius as seen rom the Observatory Ridge, May 29, 1905. From a photograph by Prof. G. Mercalli.

about 1180 metres, and both westward of the first, and nearer the station of the funicular railway.

For some weeks lava issued from these outlets and flowed down the mountain-side in two parallel streams, which from Naples had the appearance of two lines of fire running down the slope of the great cone; towards June 25 the current from "A" ceased, but the stream from "B" continued, and flows more actively than before.

On reaching the base of the great cone (800 metres), the lava piled itself up in the space between the cone and the hill formed by the lava-flow of 1895; a stream branched off, first toward Mount Somma, but afterwards in a south-south-west direction, and a small stream more fluid than the main body ran to within a short distance of the electric railway which plies between the observatory and the lower funicular station. Near the fumarole "B" a small heap of scoriæ (a driblet-cone), about 4–5 metres in height, has sprung up; but apart from the explosions attendant on its formation, and which only lasted a few days, there has been no disturbance in the regular flow of the great streams.

The line of white steam seen in Fig. 2 shows the position of the outlets and the course of the lava streams as seen from the observatory ridge; the black smoke issuing from the crater indicates the cloud of non-incandescent dust which was cast up after the partial falling in of the walls of the smaller cone on the summit.

We may perhaps attribute the frequency in these latter years of the lava streams from lateral outlets to the increased height of Vesuvius (now about 1330 metres), for the column of fluid lava, when inside the cone, is forced up to a higher level and exerts greater hydrostatic pressure on the sides of it, which are, moreover, much seamed. Formerly, when the mountain was lower, as, for instance, between the years 1840 and 1850, the lava streams generally flowed from the top.

The Millport Marine Station.

SINCE the efficiency of such an institution as a biological station is so largely dependent upon the completeness of its library, I do not think any apology need be offered for appealing to those readers of NATURE who are interested in marine biology for assistance in an endeavour to bring together for the use of those working at the Millport Marine Station as complete a collection as may be possible of works having any bearing on the fauna and flora of the European seas. The station already possesses a considerable proportion of the more important monographs, as well as a number of useful pamphlets; but there are still lacking many reference works of importance, and I am sure that copies of some of these will exist among the duplicates in many a naturalist's library. I would also urge the claims of the Millport Station upon the generosity of authors for separate copies of any papers they may publish; and in this connection it should be noted that the council of the association has recently agreed that all material intended for private research shall be supplied absolutely free of charge.

This occasion may also be utilised to point out some of the advantages which the Millport Marine Station offers to the research student. The fauna of the Clyde area is an extremely rich one, and the water in the vicinity of the station is of most remarkable purity, so that even quite delicate species can be readily kept alive in the tanks. A small steamer, the *Mermaid*, specially built for scientific research, is constantly at work during the summer months, and brings in daily an abundant supply of material. The tank-room, only part of which is open to the public, has recently been greatly extended, and now has facilities which are probably unsurpassed anywhere for the accommodation of invertebrates and the smaller vertebrates; the tanks are mostly of glazed fire-clay, and capitally adapted for observation and experiment. Besides a well-equipped private research room, there are seven screened compartments in the general laboratory affording ample accommodation for nine students, while a large class-room recently added has benches for forty-five students.

The station is lavishly equipped with apparatus of all kinds—for instance, the student will find here every facility for advanced physiological work. In fine, I think it may fairly be claimed that nowhere in the British Isles will the student find facilities for research on marine biology such as exist at Millport; and, indeed, I know of no marine station elsewhere which can, all things considered, offer greater advantages to the biologist. Lastly, it may be mentioned that although the fees are very low, there is never any difficulty in arranging for a free table.

S. PACE (Director).

Millport Marine Station, N.B.

THE TOTAL SOLAR ECLIPSE, AUGUST 30.

(1) THE SOLAR PHYSICS OBSERVATORY EXPEDITION.

Palma, August 26.

IN another four days the eclipse will be an event of the past, and we shall be packing up the great amount of material which we have been setting

FIG. 1.—Our camping ground as seen from the south-east end. n the long tent on the left is the 76 ft. prismatic reflector, and all the other instruments are beyond it. Notice the poles for the discs in the right-hand corner.

up with so much care since August 11. The greatest keenness has been displayed in every party told off for its particular duty, and I think that everyone will be glad when the eventful day arrives.

We have settled down to routine work every day. Those in charge of instruments go to the camp at about 6.15, and work at the adjustments and small items so necessary for successful photographs. At nine o'clock the whole band of volunteers, now about 150 in number, arrives at the camp, and three drills are then gone through in fairly quick succession. The organisation of the division of labour at each instrument is now very satisfactory, and the various movements that have to be performed at stated times occur in clockwork fashion.

FIG. 2.—The camp as seen from the south-west end of the ground. The 3½-inch McClean equatorial in the foreground, 16 ft. coronagraph under tent on left, 76 ft. prismatic reflector under canvas on the right. All these instruments are housed with sails and spars from H.M.S. *Venus*.

As I have mentioned before, the whole work of the camp is organised according to signals given by the

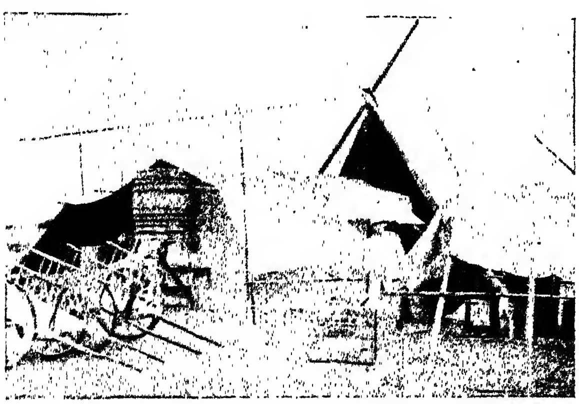

FIG. 3.—The north end of the 76 ft. prismatic reflector, showing the dark room with the wine-tub for water, the two handcarts loaned us, and on the right, under the small awning, the 3-prism 6-inch prismatic camera.

eclipse clock. There are, however, two further signals given from the angles subtended by the cusp at the centre of the dark room. These angles, which have been previously calculated, give us 16 seconds and 5 seconds respectively before the commencement of totality. The object of employing these times is not so much to assist the observers in the camp generally, as to warn the workers with the prismatic cameras, who begin making their exposures three seconds before the commencement of totality. Both Mr. Butler and myself utilise these two signals to begin our series of snap-shots for photographing the lower chromosphere.

Undoubtedly the three minutes three seconds, the length of totality at this station, is a long time, and when the strong voices of the timekeepers are heard shouting out "163 seconds," "153 seconds more," &c., one somehow feels that one is not utilising to the fullest extent the time available.

With the prismatic camera, of which I am in charge, it is hoped to secure fourteen photographs. The three large 6-inch prisms of 60°, and the object-glass of the same diameter, form together a powerful weapon of research. The programme of work is to make four snap-shots at about the commencement of totality and five about the end. The remaining five plates will be exposed for intervals varying from 5 to 90 seconds, and it is hoped that the two long exposures on each side of mid-totality will add to our knowledge of the wave-lengths of the coronal rings. This prismatic camera is designed to give results suitable for determining accurate wave-length of the chromospheric and corona arcs; the image of the sun is therefore small, and the dispersion large.

The prismatic reflector of 76 feet focal length, in charge of Mr. Butler, provides a solar image of about 8 inches diameter, and, since the light is made to pass through one prism twice, the dispersion is not excessive. The large chromospheric arcs should, however, provide us with much matter for thought.

This latter instrument is practically ready for the eclipse, and a few words may here be said as regards the erection of it. The camera end itself forms part of the dark room of the camp, and is to the south of it. Just outside, but a little to the west of the north and south line, is the siderostat, which throws the solar rays on to the long-focus mirror situated to the south about 70 feet. This concave reflector throws the image towards the north, into the portion of the dark room in which is fitted a screen. An arrangement is adopted for inserting, during some periods of totality, a prism in front of the mirror. The light from the siderostat has thus to pass twice through the prism, giving a very useful

spectrum. The large size of the image involves the use of very great photographic plates, and in this case plates 2 feet square and 2 feet by 1 foot will be used.

In order to keep out the light from the cloth tube connecting the mirror with the camera, sails have been erected on large spars, making the whole tube a very imposing structure.

Two new additions to eclipse drill have been introduced to render the organisation more perfect and flexible in exceptional circumstances, and both of these have been proved to be necessary. During one

FIG. 4.—The timekeepers at work with the eclipse clock, and their audience.

of the rehearsals the other day the eclipse clock stopped owing to the hand coming in contact with the dial over which it moves. Such an occurrence has never been known in our eclipse history before, and the timekeepers remained dumb after counting "163 seconds more." In future, a man with a stop-watch will stand with the timekeepers and keep a tally of the 10 seconds as they pass.

The second innovation was prompted by the possible absence on the day of the eclipse of any one member of a group working an instrument. Unfortunately, I

FIG. 5.—The cœlostat end of the 16 ft. coronagraph, which is under the tent on the right.

had to spend the whole of Saturday, August 26, in bed by the doctor's orders; but my instrument was very efficiently worked by the navigating officer, Lieut. Horne, who will make the cusp observations from my siderostat during the eclipse. In each party, then, the work of each member was changed, and drills were carried out under this scheme with success. I should like to take this opportunity of thanking most heartily both Staff-Surgeon Clift and Surgeon Jones, of H.M.S. *Venus,* for their very kind and efficient assistance on that occasion.

The camp at the present time practically fills the whole of the enclosed ground placed very generously at our service. Through the kindness of the local authorities, extra tents have been provided, and much material loaned in the way of wood for the shadow-band party, handcarts for the use of the men bringing water and provisions from the ship, &c.

To avoid the inconvenience of any dust arising from the road to the north of the camp, the same authorities will keep this well watered on the day of the eclipse, and for some days previous to it, and they have also arranged that the manufacturers' chimneys, which are very numerous here, shall not smoke during the time of the eclipse.

WILLIAM J. S. LOCKYER.

(2) REPORTS OF OBSERVATIONS.

Up to the time of writing very few details as to the actual scientific results obtained during the total eclipse of the sun on August 30 have arrived in this country; but it is very clear that the hopes expressed in these pages on August 24 have not been completely realised on account of the prevalence of cloud during totality at several stations.

Telegraphing from Castellon, Prof. Callendar states that, although the first and last contacts were observed in a clear sky, totality was entirely obscured by clouds. Good records of radiation and temperature were, however, secured. Similarly, Mr. Evershed, who had set up a very fine prismatic camera near to Burgos, says in a telegram to the Royal Society, "Thick clouds; no results." This forms a striking contrast to the reports of the Press correspondents, which state that all the observations at Burgos itself were successfully carried out during a temporary break in the clouds. A reproduction of a photograph of the corona, taken with a camera of 48 inches focal length by Mr. J. T. Pigg at Burgos, appeared in the *Daily News* for September 2.

At Palma, Majorca, the expedition from the Solar Physics Observatory, South Kensington, under the direction of Sir Norman Lockyer, and assisted by the officers and crew of H.M.S. *Venus,* were apparently only a little more successful, for as the crucial moment of totality arrived dense clouds came up and obliterated the sun. At about mid-totality, however, a break in the clouds occurred, and some photographs were secured which, it is hoped, may at least show the form and extent of the corona. Several good drawings of this feature, which was of the "maximum" type seen in 1871 and 1882, were made by the "disc" sketching parties.

At Saragossa, cirrus clouds prevented observations being made.

Encouraging but brief reports have been received from the observers at the North African stations.

Mr. Newall, at Guelma, appears to have been singularly fortunate, for he reports "superb weather conditions, observations successfully made," and states that he observed a brilliant corona of the "maximum" type having remarkably long streamers —one of which extended towards Mercury for more than three degrees—and unusually dark rays. Splendid prominences were also observed by him.

Sir William Christie's report from Sfax is not quite so sanguine, for he states that the sky was partially cloudy; nevertheless, photographs were secured with all instruments, and the eclipse was satisfactorily observed. A Reuter telegram from this station says that during the period of totality no clouds interfered with the observations.

At Assuan, where Prof. Turner set up his coronagraph and polariscopic apparatus, the atmospheric conditions were perfect, except for a slight haze, and the *Times* correspondent reports that eight photographs in polarised light were obtained and successful corona pictures were taken. Mr. Reynolds with his 120-feet reflector evidently experienced the great drawback common to all users of long-focus cameras, viz. bad atmospheric tremors, for the local fire brigade had to be requisitioned to flood the site in order to check the radiation from the heated ground.

Dr. J. Larmor sends us the following observations made by Mr. S. L. Walkden on the Orient steamer *Ortona*, situated on the central line of the eclipse in the Mediterranean near the Spanish coast. The observations contain a good naked-eye record of the eclipse, and agree with Dr. Larmor's impressions:—

"Rainbow colours visible on small cloud about 5° from sun about ½ minute to 1 minute before totality. Pulsation of light from strip of sun was observed by Mr. Campbell and myself as if the moon advanced by stages. (Probably another aspect of shadow-bands phenomenon.) No approach of shadow observed by myself, though keenly looked for; but found no one else who observed it except Mr. Campbell, who caught it in the sky not far from sun's limb at time of approach of totality. *Totality*.—Venus first noticed about one minute before totality, and Regulus as soon as totality complete. Mercury searched for with Zeiss field-glass and naked eye, but *not* caught after about 10 to 15 seconds' search. *Corona*.—Very fine and very detailed, so that general description difficult. *General impressions*.—(1) Some streamers seemed to cross, and were certainly not all radial. (2) Obvious extension seemed about two sun diameters. (3) Streamers distributed all round sun, but chiefly at left-top (45° from top) limb. Long thin streamer at left-left-bottom limb (67½° to left of bottom). *Prominences*.—Distributed more or less all round, but chief one observed at left-top corner. Height about ¼ of sun's radius; but this should be corrected for irradiation, which made the prominence appear to trespass into the moon's surface, exaggerating its size and producing general local glare. Colour of prominence was much less marked than expected, being merely of a violet or faintly rosy-pink hue. Shadow bands observed on deck at end of totality (looking down from boat deck). They 'rippled' along a little faster than could be easily followed by eye. They were parallel to the strip of the sun after totality, and travelled in direction of shadow. Dark strips about 6 to 8 inches wide, distance apart about 18 inches. During totality depth of darkness seemed practically independent of depth of our immersion in shadow. Clouds formed a good deal after ⅘ of sun's diameter had gone. *Lightness* of eclipse very marked, and in itself disappointing. Time by watch always plainly visible. Sky illumination greatest round horizon, and a yellow glow (like sunset) in points *opposite* to sun (about N. point). Coast lights were visible a few miles away, and one hill to N. appeared as if *perforated*, with the sky showing through. This was observed by one other passenger. Venus still visible nearly 5 minutes after end of totality. Whole black disc of moon was visible shortly before totality, say 5 to 10 seconds before."

According to a correspondent writing to the *Times*, some interesting observations of a simple character were made by the amateur astronomers on board the P. and O. mail steamer *Arcadia*, which for the time of the eclipse waited off the coast of Spain not far from Castellon. Members of the British Astronomical Association were on board, and organised themselves to watch various features of the phenomena. Mr. and Mrs. Johnson report that they saw the whole contour of the moon projected on the corona immediately after the first contact. Thermometric observations showed a fall from 90° to 72°.6 in the sun, and from 82°.4 to 72°.5 in the shade, temperature. Mr. Bacon, first officer of the *Arcadia*, made successful observations of the approach and of the recession of the moon's shadow from a point of vantage at the mast-head.

As regards the observations made by foreign astronomers, those located at Castellon, Burgos, Guelma, Sfax, and Assuan shared, of course, in the conditions enumerated above. M. Trépied, of the Algiers Observatory, was apparently very successful at Guelma, and obtained numerous photographs of the chromospheric spectrum and the corona. A fall of temperature of 5° C. (from 33° to 28°) was recorded, and Mercury, Venus, and Regulus were observed.

At Tripoli, Prof. Todd, of Amherst College Observatory, M. Liberd, of Paris, and Prof. Millosevich, of Rome, were favoured with a clear sky. Prof. Todd secured some 250 photographs of the corona with his automatic coronagraph. Very good observations of the shadow-bands are said to have been made at this station.

A disappointing feature of the eclipse was the failure to secure observations at both ends of the shadow's path. As mentioned before in these columns, arrangements had been made by the Lick Observatory to photograph the corona in Labrador and in Egypt with exactly similar coronagraphs. Mrs. Maunder, accompanying the Canadian party at Hamilton Inlet (Labrador), was also to use a coronagraph identical in scale with that used by Prof. Turner at Assuan. A Reuter telegram from St. John's, Newfoundland, announces, however, that the Lick observers experienced a total failure owing to clouds; a second message from a telegraph station on Hamilton Inlet stated that fine weather prevailed from 7 a.m. to 6 p.m. on the day of the eclipse, and that the phenomena were perfectly visible, and it was hoped that the Canadian party had been successful in making good observations. A later telegram, dated September 3, states, however, that the expedition was entirely unsuccessful, owing to the cloudy weather, and no photographs were secured.

A communication from Mr. J. Y. Buchanan, F.R.S., to the *Times* of September 5, contains some interesting notes of visual observations made during the period of totality at Torreblanca, a small village on the east coast of Spain. Having been present at the 1882 eclipse, when he assisted Sir Norman Lockyer at Sohag, on the Nile, and not having *seen* the whole of the phenomena, Mr. Buchanan only took with him an ordinary camera and a field-glass, so that he might devote all his attention to visual observations. His choice of Torreblanca, where, with the exception of the local railway employees, he seems to have been the sole observer, was justified, inasmuch as the eclipse took place in a blue sky. As the last vestige of sun disappeared behind the eastern limb of the moon a magnificent bunch of prominences, of a light violet hue, appeared at the same part of the limb; but these subsequently disappeared, and a careful search at mid-totality failed to reveal any prominences at all. A similar group, however, burst into view on the opposite limb just before the end of totality, thus indicating that the apparent diameter of the moon was sufficient to cover the whole of the prominence layer of the sun's limb at mid-totality.

The corona was clearly visible near to the western part of the moon's limb eight seconds before the advent of totality, and throughout totality it was very clearly defined. On an average it extended to rather more than one lunar diameter from the limb, but a streamer on the lower western limb was judged

to extend to at least twice this distance. The whole corona had an appearance of movement, suggesting to Mr. Buchanan certain features which occur when a search-light illuminates the atmosphere.

Observations of the partial eclipse are of no great interest as compared with those made during totality, but a number of thermometric readings were recorded at numerous stations. Mr. Spencer Russell, in a communication to the *Standard* for September 2, gives a table of fifteen-minute observations of a wet and dry bulb thermometer, made at Epsom between 11.45 a.m. and 2 p.m. on the day of the eclipse. Whilst the wet bulb readings remained constant at 53° F., the dry bulb showed a minimum temperature of 54° F. between 12.45 and 1.30 p.m. Photographs of the partial eclipse were secured by Messrs. Spencer and Butler during a balloon journey from Wandsworth to Caen in Normandy.

An interesting record of a series of "pin-hole" images of the crescent sun reaches us from Sir Joseph Fayrer, F.R.S. Whilst sailing in a ten-ton boat having a large mainsail, he observed the partial eclipse under favourable conditions in Falmouth Bay. About 1 p.m. a slight breeze caused the sail to incline from the perpendicular, and a number of well defined crescent images were projected on to the whitened deck of the boat, and occasionally on to the water. An investigation showed that these images were formed by a series of eyelet holes, used for the balance reef, high up in the sail. The phenomenon was so vivid and the images so sharply defined as to appear worthy of record.

A correspondent to the *Daily Graphic* (September 2), the Rev. Frederick Ehlvers, rector of Shaftesbury, Dorset, records the remarkable phenomenon of an evening primrose unfolding itself during the eclipse as if evening had arrived. Observers at the Solar Physics Observatory, South Kensington, were prevented by clouds from seeing the eclipse, except for one or two breaks of short duration. About one minute before last contact, however, the sky suddenly became clear for a short distance around the sun, and brilliant sunshine prevailed as the last trace of the moon left the solar disc.

TECHNICAL EDUCATION IN NATAL.[1]

THE report of the commission appointed to inquire into technical education in Natal has just been received. It is signed by eleven out of twelve of the commissioners, and Mr. C. I. Mudie, superintendent of education, has forwarded a minority report.

The commission, under the presidency of Sir David Hunter, K.C.M.G., held eleven meetings and examined fifty witnesses; some of the members were also sent to Johannesburg to confer with the council and board of studies of the Transvaal Technical Institute. Delegates from the Orange River Colony also attended the conference.

The commission finds that Natal, with its European population of 97,109, has as yet but meagre provision for technical and higher education, and, indeed, states that boys who had received primary and secondary education in the colony were frequently found to be so deficient in general knowledge that they were not well qualified to enter upon technical education.

The result of inquiries as to the probability of youths availing themselves of instruction should it be placed within their grasp was decidedly encouraging, and the commission concludes, from the evidence and statistics, and from the fact that considerable sums are being expended by individuals in Natal on American correspondence classes and private tuition, that there is an urgent necessity for more adequate provision to equip the youth of the colony for the battle of life.

The resolutions of the conference held at Johannesburg point out that there is a present and immediate need for a full teaching university in South Africa, and that the colonies in which the university may not be situated should each have one or more colleges or institutes devoted to higher or technical education which should be recognised by the university council as integral parts of that teaching university, and that the university should grant diplomas in professional subjects, and degrees in arts and science, in the faculties of (1) education; (2) engineering, including mining; (3) agriculture; (4) law; and (5) medicine.

The recommendations of the commission are based upon the resolutions of the conference, and suggest that immediate steps should be taken by the Government to provide for higher education; that a council be appointed by Government to organise and control technical education in Natal which shall be independent of the education department, although that department should be represented on the council. It suggests that specialists be obtained as lecturers in (1) chemistry and metallurgy; (2) physics and electrotechnics; (3) natural science (botany, zoology, geology, physiology); (4) pure and applied mechanics; (5) modern history and literature; while other subjects would be taught by local part-time men.

It is suggested that Pietermaritzburg has first claim for this college, but that Durban also has claims, and the commission thinks that the foregoing lecturers should be peripatetic, in the first place teaching at Pietermaritzburg and Durban only, but as occasion required going farther afield.

While appearing to have somewhat wide views as to the subjects that should be taught—for twenty-six branches are mentioned in the list of subjects in which the commission finds there is a need for classes—the estimates of cost are strictly moderate, for the annual expenditure is taken at 6500*l.*, and the initial expenditure to provide the necessary equipment for engineering, chemical, physical, natural science, and other laboratories is estimated at about 2000*l.* It is true that no provision is made in this estimate for rent or capital expenditure on buildings, but we should think even without these the estimate was likely to be exceeded.

All institutions, however, must have a beginning, and those which start with the highest aspirations have a good chance of attaining some, if not all, of their objects. There can be no doubt that technical education should be conducted everywhere quite apart from the education department, and as much as possible under the guidance of men who are acquainted with some at least of the subjects that are being taught. Technical education, especially in the colonies, should be made accessible to everyone, and should more especially offer inducements to those who are working for their living to improve their knowledge of the sciences which underlie their handicrafts. If this be the first object in view, it will be evident that evening classes and evening laboratory work must be undertaken before any attempt is made to form day classes. It appears to be chiefly on this subject that Mr. Mudie dissented from the report of the commission, for he thinks the college at Pietersburg, which, as he says, covers a preparatory, a high school, and a college proper, should form the nucleus of a university college in Natal. It would not seem to be a desirable thing to commence operations in this way for many reasons, the principal of

[1] Colony of Natal. Report of the Technical Education Commission May, 1905. (Maritzburg: P. Davis and Sons, 1905.)

which is that artisans, clerks and others, for whom technical education is primarily provided, while wishing to learn, have in many cases left school so recently that they do not wish to return, and those of maturer age are not always quite certain whether their dignity will allow them to go to school again.

THE WOBURN EXPERIMENTAL FRUIT FARM.

The fifth report on the Woburn Fruit Farm, by the Duke of Bedford and Mr. Spencer U. Pickering, F.R.S., contains a very useful summary of the results of ten years' experiments and observations on apple-trees. The conclusions arrived at are based on measurements of leaves, trees, and fruits, and also on weighings of the fruit. The average size of the leaf of the tree seems gradually to diminish with age, and there is a similar but less marked tendency in the fruit. The experiments indicate no advantage from heavy thinning of the fruit, for the size was not increased; hard pruning proved unprofitable, unpruned trees were three times more productive than those heavily pruned; summer pruning was found not to be desirable, and even moderate root pruning was found to injure the trees. Apple-trees transplanted at 2–3 years old were found to grow better than either younger or older plants.

A very curious result which for some time puzzled the experimenters was that carelessly planted trees, though weak at first, ultimately made more growth than those carefully planted. A satisfactory explanation has, however, been found. The roots of carelessly planted trees are so much injured that they make scarcely any growth; the result of this is that numerous new roots grow from dormant buds higher up the stem, and these new roots, not having suffered from transplantation, ultimately surpass in size the original roots of carefully planted trees.

The results obtained at the Woburn Fruit Farm are to some extent due to the particular soil—a moderately stiff clay—but it is probable that the conclusions arrived at would be found to hold good in many English orchards. It is, however, a very difficult thing to judge how far conclusions of the foregoing kind, based on a particular set of conditions, apply under different conditions, and the practical value of the long series of experiments and observations made at Woburn would be very greatly increased if similar experiments were conducted on a soil, or soils, of different character. In any action which the Board of Agriculture and Fisheries may take upon the report of the "Fruit" Committee, it is to be hoped that the important work of the Duke of Bedford and Mr. Pickering may be followed up and extended.

T. H. Middleton.

NOTES.

To commemorate the meeting of the British Association in South Africa, a scheme has been formulated to found a British Association medal for South African students. This announcement was made by Prof. Darwin at the close of his presidential address at Johannesburg. A visit was paid to the Johannesburg Observatory on August 30, and the opportunity was taken of pointing out to Lord Selborne the suitability of the site for a fully-equipped observatory and the necessity for more astronomical work in the southern hemisphere. Referring to this suggestion in the course of his speech introducing Prof. Darwin as president of the association, Lord Selborne is reported by the *Times* correspondent to have said that "he greatly regretted he had been obliged to refuse the only request that the association had made to him—namely, to find funds for the establishment of a proper observatory in Johannesburg. He was obliged to say that all the revenue they at present possessed was required for the development of their material resources and means of communication; but where the Government was powerless, what a magnificent opportunity there was for a patriotic Transvaal. For a site in the purest atmosphere, 2000 feet above the highest observatory now existing, only 10,000*l*. was required. There they might establish a telescope which would help observers in the southern hemisphere to compete with the astronomers of the northern hemisphere. The site was there, and it was already occupied by a perfectly equipped meteorological observatory." All the papers on South African matters read during the meeting are to be published in a separate volume by the South African Association for the Advancement of Science. At the closing meeting, held on September 1, Prof. Ray Lankester was elected president of the association for 1906.

Mr. J. W. Douglas, one of the editors of the *Entomologist's Monthly Magazine*, died at Harlesden on August 28 in his ninety-first year.

Three distinct earthquake shocks, the severest ever experienced in the district, were felt at Portsmouth, New Hampshire, on August 30, beginning at 5.40 p.m.

Reuter's correspondent at Stockholm reports that Prof. Nathorst has received a letter in which Lieut. Bergendahl, who is a member of the Duc d'Orléans's Greenland Expedition, states that on July 27, as the expedition passed Cape Bismarck, unknown land was discovered. It appears that Cape Bismarck lies on a large island, and not on the mainland. The new land has been mapped as well as possible, and has received the name Terre de France. The expedition was unable to penetrate further north than 78° 16′ N. lat.

At the annual meeting of the Academy of the Lincei, which was held on June 4 in the presence of the King and Queen of Italy, the president, Prof. Blaserna, announced the result of the competition for the three Royal prizes founded by the late King Humbert. In the section of normal and pathological physiology, the prize is awarded to Prof. Aristide Stefani, of Padua, for his published work dealing with the physiology of the heart and circulation, the non-acoustic functions of the labyrinth of the ear, and the serotherapeutic treatment of pneumonia. In the sections of archæology and of economic and social science, the judges reported that the competitors were not of sufficient merit to justify the award of the prizes. This is the first occasion on which so small a proportion of the prizes have been conferred, and it is proposed that in future the section of archæology shall embrace not only classical, but also Christian and mediæval archæology. Ministerial premiums intended to aid original work among teachers in secondary schools were awarded in the department of mathematical sciences to Prof. Ciani (50*l*.), Prof. Pirondini (38*l*.), and Prof. Chini (20*l*.). Out of the funds available from the Carpi prize, a sum of 32*l*. was awarded to Dr. P. Enriques for a thesis on the changes brought about in absorbed chlorophyll by the action of the liver, and the relation existing between the derivatives of chlorophyll produced in the organism and the genesis of the hæmatic pigments. In his address the vice-president, F. d'Ovidio, discussed in general terms the question "Art for Art's Sake," dealing more particularly with the influence exerted on national life and character by art and literature.

THE *Popular Science Monthly* (vol. lvii., No. 4) contains a suggestive article by Prof. John M. Coulter on the methods available for arousing public interest in scientific research. The results of scientific work usually reach the public through the medium of reporters to the newspapers and writers for the magazines; the material dealing with original research is, generally speaking, scant in amount, sensational in form, and wide of the mark. It is urged that men of science should, so far as possible, be their own interpreters, so that the misleading statements of the "middle man" may be avoided. Particularly, not only the facts of the investigation, but its general bearing should be made clear; it is this feature that the reporter always misses, and a "strategic movement is represented to the public as a dress parade." As a justification, it is contended that research will be shown to be practical, and a more ample endowment be secured for it. "The question of adequate support for research is the most serious one that confronts American science to-day." The appeal to American interest is utility, and it is necessary to show that practical results are reached most surely and most quickly from the vantage ground of pure science.

THE report of the commission appointed for the investigation of Mediterranean, or Malta, fever (part iii.), recently issued by the Royal Society, contains the important announcement that goats seem to be capable of transmitting the disease. The evidence supporting this conclusion is as follows:—On June 14 Dr. Zammit examined six goats, and found that the blood of five of them gave the agglutination reaction for Mediterranean fever. This was confirmed by Major Horrocks, R.A.M.C. Major Horrocks and Dr. Zammit then undertook the examination of eight different herds of goats, and in every herd examined an average of half the animals (from 7·6–75 per cent.) gave the agglutination reaction for Mediterranean fever. It was also found that one or more apparently healthy goats in every herd were excreting the specific organism of the disease—the *M. melitensis*—in their milk and urine, the number of the organism in the milk being very large. It would seem probable, therefore, that infected goat's milk may be the source of infection of man, particularly as monkeys may be artificially infected by feeding with material containing the specific organism, as has been detailed in a previous report. It is of interest that in Gibraltar, where the disease is also very prevalent, goats are almost the only source of the milk-supply.

THE report of the Government analyst of Trinidad for the year 1904–5 contains several points of general interest. Samples of water from the Carrera Convict Depôt have been examined to ascertain if a connection could be traced between the water supply and the prevalence of diarrhœa and dysentery among the prisoners. Very small proportions of lead, copper, and zinc were found to be present, and, in view of the fact that all attempts made during several years past to trace the epidemic to other causes have been unsuccessful, it appears possible that the metallic impurities named are responsible for the trouble. Before the question can be definitely decided, further investigation will be necessary. The aërated waters which are largely consumed in the colony were found to be usually contaminated with lead, owing to the use of an impure sulphuric acid in their manufacture, to an extent likely to prove dangerous. It is suggested that the use of liquefied carbon dioxide, such as is now imported into the colony in cylinders, would be a remedy for the difficulty. The adulteration of milk has very much decreased owing to the system adopted of suspending the licenses of sellers convicted of adulteration during the past year. Previously the Board of Health did not refuse the renewal of licenses, either temporarily or permanently, but only issued warnings.

THE fishes of Puget Sound form the subject of a paper by Messrs. Gilbert and Thompson in the *Proceedings of the U.S. Nat. Museum* (No. 1414). The paper is based on a collection made in 1903, which included two species regarded as new and six not previously recorded from the area in question.

THE opening article in the first part of the third volume of the quarterly issue of *Smithsonian Miscellaneous Contributions* is a translation of Dr. E. Mascha's valuable paper on the minute structure of the flight-feathers of birds, originally published in the *Zeitschrift für wissenschaftliche Zoologie*, and already noticed in our columns. Among the original communications, special reference may be made to one by Mr. F. W. True on the skull of an extinct sea-lion (Pontoleon) from the Miocene of Oregon, apparently the earliest known representative of this group of seals; to a second, by Mr. A. Mann, describing the extreme beauty of the surface sculpture in diatoms ("Diatoms, the Jewels of the Plant-World," it is called); and to a third, by Mr. C. A. White, on the ancestry of the North American pond-mussels of the family Unionidæ, in which it is concluded that all the living forms in this particular area are descended from fossil local types. It may be added that if we accept the views on nomenclature expressed in yet another article, the well known name Dromæus (for the emeu) has to give place to Dromiceius.

THE *Proceedings of the American Philosophical Society*, Philadelphia (xlix., No. 179), contains papers on the Filipino, on the Aborigines of Western Australia, on the osteology of sinopa, and on the marsupial fauna of the Santa Cruz beds. In an article on the oligodynamical action of copper foil on certain intestinal organisms, Mr. Kraemer concludes that intestinal bacteria such as the colon and typhoid bacilli are completely destroyed by placing clean copper foil in water containing them, and that certain of the lower animal and vegetable organisms possess a special sensitiveness to minute quantities of copper. The copper is probably in the form of a crystalloid rather than that of a colloid. It will be remembered that Dr. Moore, of the United States Department of Agriculture, has suggested the use of copper salts and of bright copper for the purification of water supplies. In another article Dr. Wiley discusses the effects of preservatives in food on metabolism, and expresses the opinion that boric acid and borates in any quantity upset digestion, and even in small doses, if given over a long period, have an unfavourable effect on health and digestion.

A PAPER by Dr. W. T. Calman, of the British Museum, on the Crustacea of the group Cumacea from the west coast of Ireland, published as No. 1, part iv., of Scientific Investigations, 1904, by the Irish Department of Agriculture and Technical Instruction, illustrates the importance of collecting on a thoroughly practical and effective system. During the entire cruise of H.M.S. *Challenger*, for instance, the whole collection of Cumacea was represented by no more than fifteen species, whereas Mr. E. Holt, the collector of the specimens submitted to Dr. Calman, obtained within a small area representatives of no less than forty-eight species, of which nine are regarded as new, one being so aberrant as to be assigned by its

describer to a separate family group. Most of the specimens were collected by means of tow-nets attached to the back of a trawl in such a position as to capture any creatures disturbed by the ground-rope.

In the report on the sea and inland fisheries of Ireland for 1902 and 1903, part iii., scientific investigations, Mr. E. W. L. Holt, the scientific adviser of the fisheries branch of the Board of Agriculture and Technical Instruction for Ireland, takes a broad view of the services which scientific investigations can render to practical fishery problems. Not only are such subjects as oyster culture, the artificial propagation of the Salmonidæ, and the mackerel fisheries dealt with, but the various appendices to the report constitute a most valuable addition to our knowledge of the invertebrate marine fauna of Ireland, more especially of the very interesting and little-known fauna occurring in the deeper water off the west coast. The most important paper, from a scientific point of view, is that contributed by Mr. Holt himself, in collaboration with Mr. W. M. Tattersall, on the schizopodous crustacea of the north-east Atlantic slope, in which a great number of new or little known species are fully described and figured. Other papers deserving special notice are Mr. G. P. Farran's account of the copepoda of the Atlantic slope, and the interesting contributions of the Misses Delap on the rearing of *Cyanea lamarcki* and on the plankton of Valencia Harbour from 1899 to 1901. The whole report, which treats of both sea- and fresh-water fisheries, is well illustrated with a large number of plates and diagrams excellently reproduced, and reflects great credit upon the department responsible for the scientific study of the Irish fisheries.

The *Pioneer Mail* of July 28 published an account of the phenomenal storm of wind and rain which devastated a large portion of the province of Gujarat between July 22 and 24, owing to which it was estimated that about 10,000 people were rendered homeless. The storm seems to have been most severe at Ahmedabad, 310 miles north of Bombay. The average annual rainfall of that place is only about 33 inches; during the storm in question it was stated that fully 37 inches were measured in two days. We find from the Official *Indian Daily Weather Report* that the fall was over-stated, but that nevertheless it was quite abnormal; 14 inches fell in twenty-four hours ending 8h. a.m. July 23, and 12½ inches on the following day. The Government meteorological reporter states that the fall was due to a severe cyclonic storm passing over the head of the peninsula, and to the fact that when it entered Gujarat it was fed by strong winds from the Arabian Sea.

We have received "British Rainfall, 1904," being the forty-fourth annual volume of this very useful publication, containing the carefully prepared results of observations taken at nearly 4000 stations. Dr. Mill states that every return undergoes critical examination before the results are published, a task that must strain the energies of himself and his small available staff to the utmost. While every page of this now somewhat voluminous work contains information of the highest value in connection with the distribution of rain over the British Isles, it is difficult to fix upon any particular portion calling for especial remark. One new feature is the publication of complete daily records for ten selected stations, and, as last year, attention has been given to a discussion of some of the wettest days, illustrated by special charts. There are also several interesting articles dealing with various branches of rainfall work, *e.g.* an analysis of the observations on the summit of Ben Nevis and at the base station at Fort William, for the years 1885–1903; for more complete details reference is made to an exhaustive discussion published by Mr. A. Watt in the *Journal of the Scottish Meteorological Society*. Another article deals with October rainfalls; this is generally the wettest month of the year over the greater part of England. In the present case, special reference is made to the comparatively dry Octobers of 1879, 1888, 1897, and 1904; with one exception, October, 1904, was the driest on record since the foundation of the British rainfall organisation. Another important article discusses the duration and average rate of rainfall in London since 1881. It shows *inter alia* that the rate of fall per hour is twice as great in July as in January.

We are glad to be able to reproduce from the *Annuario* of the Messina Observatory for the year 1904 an illustration of that important Sicilian station, which, under the able superintendence of Prof. Rizzo, undertakes, in addition to the usual meteorological observations, valuable

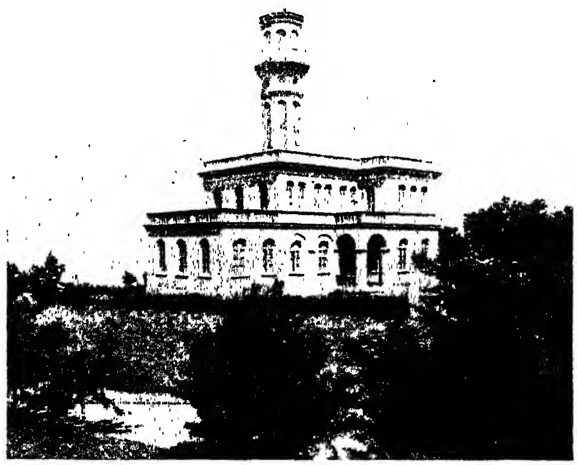

Fig. 1.—The Messina Observatory.

researches connected with solar and terrestrial physics. The institution has risen from modest beginnings in 1876, when, at the instigation of Prof. Manzi, it was attached to the Technical and Nautical Institute of that city. The importance of its work was soon recognised by the Central Meteorological Office at Rome, which supplied it with several instruments. The present edifice on the hill of Andria was completed in 1902, under the auspices of the Royal University of Studies at Messina, and occupies a position much better suited to its useful work; it is now removed from all disturbing influences, and we look forward with confidence to important results connected with the relation of magnetism to solar activity and to the movements of the ground, to which subjects Prof. Rizzo devotes special attention.

The International Council for the Exploration of the Sea continues to issue its publications in rapid succession. Of the Bulletins, which embody the records of the work more especially entrusted to it, we have received those for the terminal expeditions in November, 1904, and February, 1905 (Conseil Permanent International pour l'Exploration de la Mer, Bulletin, 1904–5, Nos. 2 and 3). We note, as additions to the routine observations of the council, an

extension of the surface observations made by merchant steamers on various routes, and a series of observations in February, 1905, made and communicated by the fishery branch of the Department of Agriculture and Technical Instruction for Ireland. It can serve no useful purpose to attempt the general discussion of the observations contained in these Bulletins as they appear; the general results can best be summarised at a later stage by the central authority, by whom the work will no doubt be undertaken. For the two dates concerned, a very marked feature of the observations in the English area is worth pointing out—the high salinity of the water at the entrance to the channel and to the west of Ireland. The origin of this salt water demands close investigation; it would seem to have come almost directly from the south, and in that event it is to be hoped that means of ascertaining whether Mediterranean water was present or not are available.

THE *Psychological Review* (article section) contains in its July number the following articles:—The synthetic factor in tactual space perception, T. H. Haines; consciousness and its object, F. Arnold; and a motor theory of rhythm and discrete succession (i.), R. H. Stetson. The first of these tabulates the results of certain preliminary experiments made by the writer in order to discover the exact relation between the two sorts of synthetic factor for local signs, viz. inner tactual sensations and the visual image. The main positions of the second article are these:—(1) Neither by introspection nor by any hypothesis of a consciousness aware of its own stream can we have any mental state in which consciousness does not have an object, and that object in the present; (2) the same holds for feeling and emotion; (3) the relation of thing to consciousness cannot be represented by any simple formulation like *aRx*, but is in reality much more complex.

THE July number of *Mind* contains an excellent article by Mr. R. F. Alfred Hoernlé on Pragmatism *v.* Absolutism, which is mainly occupied with a discussion of Mr. Bradley's views. The writer finds fault with Mr. Bradley's use of the criterion of non-contradiction, his neglect of epistemology in favour of metaphysics, his doctrine of "degrees of truth and reality," and his theory that "a self-consistent reality must *include* the appearances, and yet cannot be its appearances." Dr. Norman Smith, in a second article on the naturalism of Hume, deals sympathetically with Hume's treatment of ethics. He claims that "Hume may, indeed, be regarded, even more truly than Kant, as the father of all those subsequent philosophies that are based on an opposition between thought and feeling, truth and validity, actuality and worth." Other articles deal with Empiricism and the Absolute, Plato's view of the soul, and Symbolic Reasoning.

THE *Journal of the Anthropological Institute* (July–December, 1904) contains the Huxley lecture for 1904, presented by Dr. Deniker, the subject being "Les Six Races composant la Population actuelle de l'Europe." This is virtually a re-statement and a vindication of the racial division which was propounded by Dr. Deniker eight years ago in "Les Races européennes" (*Bull. Soc. d'Anthr.*, Paris, iv., 3), which the researches of later years have served to illustrate and confirm. To the Nordic, Ibero-Insular, and Western or Cevenole races (corresponding to the Northern, Mediterranean, and Central or Alpine races of other authors) are added three main races:—Eastern, brachycephalic, short and fair; Littoral or Atlanto-Mediterranean, mesocephalic, tall and dark; and Adriatic, brachycephalic, tall and dark. There are also four secondary races:—Sub-Nordic, brachycephalic, short and fair; Vistulan, brachycephalic, very short, fair or medium; North-Western, mesocephalic or brachycephalic, tall, medium or dark; and Sub-Adriatic, brachycephalic, and medium in stature and pigmentation. The maps of the average stature and pigmentation for Europe which accompany the paper are scarcely satisfactory. The cardinal principle laid down by Prof. Ripley, that the visual impression must, so far as possible, conform to the represented facts, has not been successfully followed, with the result that in the bewildering mass of detail no general impression can be gained by the eye without the assistance of the convention in the legend.

THE *Journal of the Franklin Institute* for August (clx., No. 2) contains papers of more or less interest, and covering most of the branches of science. Mr. Fuller discusses in a very complete manner the subject of sewage disposal and the pollution of shell-fish. A very full bibliography is appended to his paper.

WE have received from the Sytam Fittings Co., of Basinghall Buildings, Leeds, the catalogue of the company's system of filing, classifying, and indexing bottles, boxes, specimens, tubes, apparatus, &c. The company has applied the characteristics of the well known elastic or expansion series of bookcases to the purposes named, the specimen cabinets being built up of a number of interchangeable elements.

THE *Johns Hopkins Hospital Bulletin* for August (xvi., No. 173) contains an interesting account, by Dr. MacCallum, of the life and work of Marcello Malpighi, with full-plate portrait of this distinguished Italian anatomist of the seventeenth century. The concluding sentence of this article may be quoted:—"After all is considered the most enduring things in Malpighi's books are his perfect honesty, his extraordinary keenness and good sense in the interpretation of what he saw, and his ingenious objective methods of observation. What he saw could not have failed of being seen very soon by others, but we are filled with wonder that quite alone, with his 'quiet, eager mind,' he could have encompassed all, steadily searching out one thing after another throughout his forty years of restless activity."

WE have received the report of the second meeting of the South African Association for the Advancement of Science. It forms a handsome cloth-bound volume of 598 pages with 44 plates, and contains the forty-four papers read before the association printed in full. Summaries of the papers were published in NATURE (vol. lxx. p. 41) shortly after the meeting, and also the greater part of Mr. E. B. Sargant's address on the education of examiners (vol. lxx. p. 63). The presidential address by Sir Charles Metcalfe, and the sectional addresses by Mr. J. R. Williams on the metallurgy of the Rand, by Dr. G. S. Corstorphine on the history of stratigraphical investigation in South Africa, and by Sir Percy Girouard on improvements in rolling stock, are of permanent value, and the subjects and names of the authors of the papers make the volume an important addition to scientific literature, and show what a large amount of valuable scientific work is being done in South Africa. The illustrations are excellent. The coloured plates accompanying Dr. L. G. Irving's paper on miners' phthisis are admirably reproduced, as also are the photomicrographs of blue ground illustrating the paper by Mr. H. Kynaston and Mr. A. L. Hall on the geological features of the diamond

pipes of the Pretoria district. This paper is of special interest. In the Premier pipe a remarkable bar of purple quartzite, locally known as floating reef, occurs. It appears to be a mass of Waterberg sandstone that has dropped into the pipe. The blue ground is considered to be a serpentinised peridotite breccia with a specific gravity of 2·757. That of the Kimberley blue is 2·734.

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A NOVA.—A telegram from the Kiel Centralstelle, dated September 1, announces the discovery of a new star, by Mrs. Fleming at Harvard, on August 12. Its position, referred to the equinox of 1900, is given as follows:—

R.A. = 284° 2′ = 18h. 56·1m.
Dec. = −4° 34′,

and, although the magnitude is not mentioned, the Nova is said to be fading rapidly.

The position given above is near to that of λ Aquilæ, the Nova apparently forming the apex of an equilateral

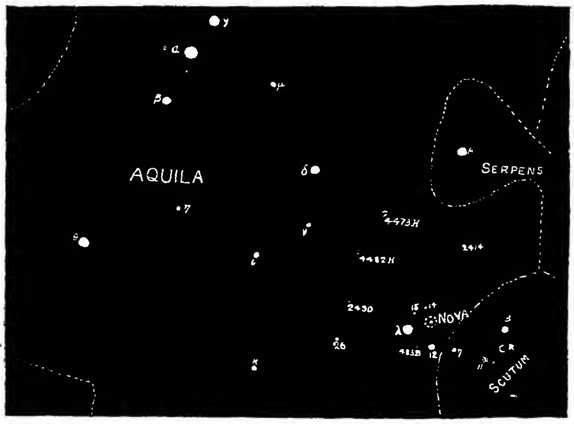

FIG. 1.—Chart of region about Nova discovered by Mrs. Fleming, August, 1905.

triangle which is completed by λ and 12 Aquilæ. The accompanying chart of the surrounding region shows the approximate position of the object.

A later telegram from Prof. Pickering gives the value R.A. = 18h. 57m. 8s. as being more correct for the right ascension of this object.

WATER VAPOUR IN THE MARTIAN ATMOSPHERE.—In Bulletin No. 17 of the Lowell Observatory, Mr. Lowell describes a new spectroscopic method for testing the presence of water vapour in the atmosphere of Mars, and Mr. Slipher discusses the results obtained from an experimental trial of the method. The principles involved are as follows:—Cosmically considered, the earth's atmosphere is at rest as regards a terrestrial observer, whilst the Arean atmosphere partakes of the planet's motion relative to the earth. This relative motion should be reflected in the solar spectrum, as obtained on a spectrogram of Mars, by a displacement of the lines due to the selective absorption common to both atmospheres. But in the terrestrial atmosphere water vapour accounts for a great deal of this absorption; therefore, if water vapour also exists in the Martian atmosphere the lines due to it should show a displacement, or at least a broadening, of such lines as those in the α band of the solar spectrum, or, with small dispersion, an extension on one side or the other of the band itself. The spectrum of the sunlight reflected by the moon, the approach or recession of which is negligible, is taken as the comparison spectrum, in which the earth's atmospheric absorption appears alone.

Mr. Slipher obtained several spectrograms of Mars and of the moon, the exposures being made when the respective bodies were at the same altitude. An examination of the α band and of the water vapour lines near D in both spectra seemed to indicate a slight shift, but the measurements made were uncertain and discordant, and no definite conclusion could be arrived at. So far as selective absorption is concerned, the spectrum of Mars seems to be the same as that of the equally high moon. Similar experiments on the planet Venus, using direct sunlight for the comparison spectrum, were equally inconclusive.

REAL PATHS OF LYRID METEORS.—The real paths of forty April meteors, recorded during the period 1889–1903 by different observers, are given by Mr. Denning in the *Observatory* (August). Many of the objects observed were Lyrids, and Mr. Denning emphasises the importance of this shower and its contemporaries, and, further, gives a daily ephemeris for the Lyrid radiant, based on his own observations of 703 meteors (186 Lyrids) during the years 1873–1904. This ephemeris covers the period April 15–April 25, but its author is doubtful of the radiant's activity on April 15, 16, and 25. On April 15 the computed position is $\alpha = 263\frac{1}{2}°$, $\delta = 33°$, and the latter value is constant. The right ascension, however, increases at the uniform rate of one and a quarter degrees per day.

OBSERVATIONS OF SATELLITES.—In No. 4035 of the *Astronomische Nachrichten* Dr. C. W. Wirtz publishes the results of a series of observations of various satellites made with the 49 cm. (about $19\frac{1}{2}$-inch) refractor of the Strassburg Observatory during 1902, 1903, 1904, and 1905. The results are given in a tabulated form, showing the differences between the calculated and observed position angles and distances. Dealing with Neptune's satellite, Dr. Wirtz found that it exhibits a marked variation of apparent brightness according to its position in its orbit. In longitude 40° (or position angle 60°) it is brightest, in longitude 240° (*i.e.* position angle 180°) it is least bright. Saturn's satellites, iii.–viii. inclusive, are also dealt with, the positions with regard to the planet and then to each other being given.

THE BRITISH ASSOCIATION.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY COLONEL SIR C. SCOTT MONCRIEFF, K.C.S.I., K.C.M.G., R.E., LL.D., PRESIDENT OF THE SECTION.

SCIENCE has been defined as the medium through which the knowledge of the few can be rendered available to the many; and among the first to avail himself of this knowledge is the engineer. He has created a young science, the offspring, as it were, of the older sciences, for without them engineering could have no existence.

The astronomer, gazing through long ages at the heavens and laying down the courses of the stars, has taught the engineer where to find his place on the earth's surface.

The geologist has taught him where he may find the stones and the minerals which he requires, where he may count on firm rock beneath the soil to build on, where he may be certain he will find none.

The chemist has taught him of the subtle gases and fluids which fill all space, and has shown him how they may be transformed and transfused for his purposes.

The botanist has taught him the properties of all trees and plants, "from the cedar tree that is in Lebanon even unto the hyssop that springeth out of the wall."

And all this knowledge would be as nothing to the engineer had he not reaped the fruits of that most severe of all pure and noble sciences—the science of numbers and dimensions, of lines and curves and spaces, of surfaces and solids—the science of mathematics.

Were I to attempt in the course of a single address to touch on all the many branches of engineering, I could do no more than repeat a number of platitudes, which you know at least as well as I do. I think, then, that it will be better to select one branch, a branch on which comparatively little has been written, which has, I understand, a special interest for South Africa, and which has occupied the best years of my life in India, Southern Europe, Central Asia, and Egypt—I mean the science of irrigation. My

subject is water—living, life-giving water. It can surely never be a dry subject; but we all know that with the best text to preach on the preacher may be as dry as dust.

Irrigation: What it Means.

Irrigation may be defined as the artificial application of water to land for the purposes of agriculture. It is, then, precisely the opposite of drainage, which is the artificial removal of water from lands which have become saturated, to the detriment of agriculture. A drain, like a river, goes on increasing as affluents join it. An irrigation channel goes on diminishing as water is drawn off it. Later on I shall show you how good irrigation should always be accompanied by drainage.

In lands where there is abundant rainfall, and where it falls at the right season of the year for the crop which it is intended to raise, there is evidently no need of irrigation. But it often happens that the soil and the climate are adapted for the cultivation of a more valuable crop than that which is actually raised, because the rain does not fall just when it is wanted, and there we must take to artificial measures.

In other lands there is so little rain that it is practically valueless for agriculture, and there are but two alternatives—irrigation or desert. It is in countries like these that irrigation has its highest triumph; nor are such lands always to be pitied or despised. The rainfall in Cairo is on an average 1·4 inches per annum, yet lands purely agricultural are sold in the neighbourhood as high as 150*l.* an acre.

This denotes a fertility perhaps unequalled in the case of any cultivation depending on rain alone, and this in spite of the fact that the Egyptian cultivator is in many respects very backward. The explanation is not far to seek. All rivers in flood carry along much more than water. Some carry alluvial matter. Some carry fine sand. Generally the deposit is a mixture of the two. I have never heard of any river that approached the Nile in the fertilising nature of the matter borne on its annual floods; with the result that the plains of Egypt have gone on through all ages, with the very minimum of help from foreign manures, yielding magnificent crops and never losing their fertility. Other rivers bring down little but barren sand, and any means of keeping it off the fields should be employed.

Primitive Means of Irrigation.

The earliest and simplest form of irrigation is effected by raising water from a lake, river, or well, and pouring it over the land. The water may be raised by any mechanical power, from the brawny arms of the peasant to the newest pattern of pump. The earliest Egyptian sculptures show water being raised by a bucket attached to one end of a long pole, turning on an axis with a heavy counterpoise at the other end. In Egypt this is termed a *shadoof*, and to this day, all along the Nile banks, from morning to night brown-skinned peasants may be seen watering their fields in precisely this way. Tier above tier they ply their work so as to raise water 15 or 16 feet on to their land. By this simple contrivance it is not possible to keep more than about 4 acres watered by one *shadoof*, so you may imagine what an army is required to irrigate a large surface. Another method, largely used by the natives of Northern India, is the shallow bucket suspended between two strings, held by men who thus bale up the water. A step higher is the water-wheel, with buckets or pots on an endless chain around it, worked by one or a pair of bullocks. This is a very ordinary method of raising the water throughout the East, where the water-wheel is of the rudest wooden construction and the pots are of rough earthenware. Yet another method of water-raising is very common in India from wells where the spring level may be as deep as 100 feet or more. A large leathern bag is let down the well by a rope passing over a pulley and raised by a pair of bullocks, which haul the bag up as they run down a slope the depth of the well. An industrious farmer with a good well and three pairs of good bullocks can keep as much as 12 acres irrigated in Northern India, although the average is much less there. The average cost of a masonry well in India varies from 20*l.* to 40*l.*, according to the depth required. But it is obvious that in many places the geological features of the country are such that well-sinking is impracticable. The most favourable conditions are found in the broad alluvial plains of a deltaic river, the subsoil of which may be counted on as containing a constant supply of water.

Pumps and Windmills.

All these are the primitive water-raising contrivances of the East. Egypt has of late been more in touch with Western civilisation, and since its cotton and sugar-cane crops yield from 6*l.* to 8*l.* or even 10*l.* per acre, the well-to-do farmer can easily afford a centrifugal pump worked by steam power. Of these there are now many hundreds, fixed or portable, working on the Nile banks of Egypt. Where wind can be counted on the windmill is a very useful and cheap means of raising water. But everything depends on the force and the trustworthiness of the wind. In the dry Western States of America wind power is largely used for pumping. It is found that this power is of little use if its velocity is not at least six miles per hour. (The mean force of the wind throughout the whole United States is eight miles per hour.) Every windmill, moreover, should discharge its water into a tank. It is evident that irrigation cannot go on without cessation day and night, and it may be that the mill is pumping its best just when irrigation is least wanted. The water should, therefore, be stored till required. In America it is found that pumping by wind power is about two-thirds of the cost of steam power. With a reservoir 5 to 15 acres may be kept irrigated by a windmill. Without a reservoir 3 acres is as much as should be counted on. Windmills attached to wells from 30 to 150 feet deep cost from 30*l.* to 70*l.*

Artesian Wells.

Up to now the artesian well cannot be counted on as of great value for irrigation. In the State of California there are said to be 8097 artesian wells, of a mean depth of 210 feet, discharge 0·12 cubic feet per second, and original cost on an average 50*l.* Thirteen acres per well is a large outturn.

In Algeria the French have bored more than 800 artesian wells, with a mean depth of 142 feet, and they are said to irrigate 50,000 acres. But these are scattered over a large area. Otherwise, the gathering ground would probably yield a much smaller supply to each well than it now does. In Queensland artesian wells are largely used for the water supply of cattle stations, but not for irrigation.

Well Irrigation.

It is evident that where water has to be raised on to the field there is an outlay of human or mechanical power which may be saved if it can be brought to flow over the fields by gravitation. But there is one practical advantage in irrigating with the water raised from one's own well or from a river. It is in the farmer's own hands. He can work his pump and flood his lands when he thinks best. He is independent of his neighbours, and can have no disputes with them as to when he may be able to get water and when it may be denied to him. In Eastern countries, where corruption is rife among the lower subordinates of government, the farmer who sticks to his well knows that he will not require to bribe anyone; and so it is that in India about 13 millions of acres, or 30 per cent. of the whole annual irrigation, is effected by wells. Government may see fit to make advances to enable the farmer to find his water and to purchase the machinery for raising it; or joint-stock companies may be formed with the same object. Beyond this all is in the hands of the landowner himself.

Canal Irrigation.

Irrigation on a large scale is best effected by diverting water from a river or lake into an artificial channel, and thence on to the fields. If the water surface of a river has a slope of 2 feet per mile, and a canal be drawn from it with a surface slope of 1 foot per mile, it is evident that at the end of a mile the water in the canal will be 1 foot higher than that in the river; and if the water in the river is 10 feet below the plain, at the end of 10 miles the water in the canal will be flush with the plain, and henceforth irrigation can be effected by simple gravitation.

When there is no question of fertilising deposit, and only pure water is to be had, the most favourable condition of

irrigation is where the canal or the river has its source of supply in a great lake. For, be the rainfall ever so heavy, the water surface in the lake will not rise very much, nor will it greatly sink at the end of a long drought. Where there is no moderating lake, a river fed from a glacier has a precious source of supply. The hotter the weather, the more rapidly will the ice melt, and this is just when irrigation is most wanted.

Elsewhere, if crops are to be raised and the rain cannot be counted on, nor well irrigation be practised, water storage becomes necessary, and it is with the help of water storage that in most countries irrigation is carried on.

Water Storage.

To one who has not given the subject attention, surprise is often expressed at the large volume of water that has to be stored to water an acre of land. In the case of rice irrigation in India, it is found that the storage of a million cubic feet does not suffice for more than from 6 to 8 acres. For the irrigation of wheat about one-third this quantity is enough. It would never pay to excavate on a level plain a hollow large enough to hold a million cubic feet of water. It is invariably done by throwing a dam across the bed of a river or a valley and ponding up the water behind it. Many points have here to be considered: the length of dam necessary, its height, the material of which it is to be constructed, the area and the value of the land that must be submerged, the area of the land that may be watered. The limits of the height of a dam are from about 150 to 15 feet. If the slope of the valley is great it may be that the volume which can be ponded up with a dam of even 150 feet is inconsiderable, and the cost may be prohibitory. On the other hand, if the country is very flat, it may be that a dam of only 20 feet high may require to be of quite an inordinate length, and compensation for the area of land to be submerged may become a very large item in the estimate. I have known of districts so flat that in order to irrigate an acre more than an acre must be drowned. This looks ridiculous, but is not really so, for the yield of an irrigated acre may be eight or ten times that of an unirrigated one; and after the storage reservoir has been emptied it is often possible to raise a good crop on the saturated bed.

The advantage of a deep reservoir is, however, very great, for the evaporation is in proportion to the area of the surface, and if two reservoirs contain the same volume of water, and the depth of one is double that of the other, the loss by evaporation from the shallow one will be double that of the deep one. In India, from time immemorial, it has been the practice to store water for irrigation, and there are many thousands of reservoirs, from the great artificial lakes holding as much as 5000 or 6000 millions of cubic feet, down to the humble village tank holding not a million. There are few of which the dam exceeds 80 feet in height, and such are nearly always built of masonry or concrete. For these it is absolutely necessary to have sound rock foundations. If the dam is to be of earth, the quality of the soil must be carefully seen to, and there should be a central core of puddle resting on rock and rising to the maximum height of water surface. If the dam is of masonry, there may perhaps be no harm done should the water spill over the top. If it is of earth, this must never happen, and a waste weir must be provided, if possible cut out of rock or built of the best masonry, and large enough to discharge the greatest possible flood. More accidents occur to reservoirs through the want of sufficient waste weirs or their faulty construction than from any other cause.

As important as the waste weir are the outlet sluices through which the water is conveyed for the irrigation of the fields. If possible they should be arranged to serve at the same time as scouring sluices to carry off the deposit that accumulates at the bottom of the reservoir. For, unless provided with very powerful scouring sluices, sooner or later the bed of the reservoir will become silted up, and the space available for water storage will keep diminishing. As this happens in India, it is usual to go on raising the embankment (for it does not pay to dig out the deposit), and so the life of a reservoir may be prolonged for many years. Ultimately it is abandoned, as it is cheaper to make a new reservoir altogether than to dig out the old one.

Italian Irrigation.

For the study of high-class irrigation there is probably no school so good as is to be found in the plains of Piedmont and Lombardy. Every variety of condition is to be found here. The engineering works are of a very high class, and from long generations of experience the farmer knows how best to use his water.

The great river Po has its rise in the foothills to the west of Piedmont. It is not fed from glaciers, but by rain and snow. It carries with it a considerable fertilising matter. Its temperature is higher than that of glacial water—a point to which much importance is attached for the very valuable meadow irrigation of winter. From the left bank of the Po, a few miles below Turin, the great Cavour Canal takes its rise, cutting right across the whole drainage of the country. It has a full-supply discharge of 3800 cubic feet per second; but it is only from October to May that it carries anything like this volume. In summer the discharge does not exceed 2200 cubic feet per second, which would greatly cripple the value of the work were it not that the glaciers of the Alps are melting then, and the great torrents of the Dora Baltea and Sesia can be counted on for a volume exceeding 6000 cubic feet per second.

Lombardy is in no respects worse off than Piedmont for the means of irrigation; and its canals have the advantage of being drawn from the lakes Maggiore and Como, exercising a moderating influence on the Ticino and Adda rivers, which is sadly wanted on the Dora Baltea. The Naviglio Grande of Lombardy is drawn from the left bank of the Ticino, and is used largely for navigation, as well as irrigation. It discharges between 3000 and 4000 cubic feet per second, and nowhere is irrigation probably carried on with less expense. From between Lake Maggiore and the head of the Naviglio Grande a great new canal, the Villoresi, has been constructed during the last few years with head sluices capable of admitting 6700 cubic feet per second, of which, however, 4200 cubic feet have to be passed on to the Naviglio Grande. Like the Cavour Canal, the Villoresi crosses all the drainage coming down from the foothills to the north. This must have entailed the construction of very costly works.

Irrigation in Northern India.

It is in India that irrigation on the largest scale is to be found. The great plains of Northern India are peculiarly well adapted for irrigation, which is a matter of life and death to a teeming population all too well accustomed to a failure of the rain supply.

The Ganges, the Jumna, and the great rivers of the Punjab have all been largely utilised for feeding irrigation canals. The greatest of these, derived from the river Chenab, and discharging from 10,500 to 3000 cubic feet per second, was begun in 1889, with the view of carrying water into a tract entirely desert and unpopulated. It was opened on a small scale in 1892, was then enlarged, and ten years after it irrigated in one year 1,829,000 acres, supporting a population of 800,000 inhabitants, colonists from more congested parts of India.

The Ganges Canal, opened in 1854, at a time when there was not a mile of railway, and hardly a steam engine within a thousand miles, has a length of about 9900 miles, including distributing channels. It was supplemented in 1878 by a lower canal, drawn from the same river 130 miles further down, and these two canals now irrigate between them 1,700,000 acres annually. On all these canals are engineering works of a very high class. The original Ganges Canal, with a width of bed of 200 feet, a depth of 10 feet, and a maximum discharge of 10,000 cubic feet per second, had to cross four great torrents before it could attain to the watershed of the country, after which it could begin to irrigate. Two of these torrents are passed over the canal by broad super-passages. Over one of them the canal is carried in a majestic aqueduct of fifteen arches, each of 50 feet span; and the fourth torrent, the most difficult of all to deal with, crosses the canal at the same level, a row of forty-seven floodgates, each 10 feet wide, allowing the torrent to pass through and out of the canal.

Elsewhere there are rivers in India, rising in districts subject to certain heavy periodical rainfall, and carrying their waters on to distant plains of very uncertain rainfall. At a small expense channels can sometimes be constructed drawing off from the flooded river water sufficient thoroughly to saturate the soil, and render it fit to be ploughed up and sown with wheat or barley, which do not require frequent watering. The canal soon dries up, and the sown crop must take its chance; but a timely shower of rain may come in to help it, or well irrigation may mature the crop. These, which are known in India as inundation canals, are of high value.

Southern India.

In Southern India there are three great rivers, drawing their supply from the line of hills called the Ghats, running parallel to and near the western coast, and after a long course discharging into the Bay of Bengal on the east coast. Against the Ghats beats the whole fury of the tropical S.W. monsoon, and these rivers for a few months are in high flood. As they approach the sea they spread out in the usual deltaic form. Dams have been built across the apex of these deltas, from which canals have been drawn, and the flood waters are easily diverted over the fields, raising a rice crop of untold value in a land where drought and famine are too common. But for the other months of the year these rivers contain very little water, and there is now a proposition for supplementing them with very large reservoirs.

A very bold and successful piece of irrigation engineering was carried out a few years ago in South India, which deserves notice. A river named the Periyar took its rise in the Ghats, and descended to the sea on the west coast, where there was no means of utilising the water, and a good deal of money had periodically to be spent in controlling its furious floods. A dam has now been built across its course, and a tunnel has been made through the mountains, enabling the reservoir to be discharged into a system of canals to the east, where there is a vast plain much in need of water.

In the native State of Mysore, in Southern India, there are on the register about 40,000 irrigation reservoirs (or tanks, as they are called), or about three to every four square miles, and the nature of the country is such that hundreds may be found in the basin of one river—small tanks in the upper branches and larger ones in the lower, as the valley widens out—and these require constant watchful attention. From time to time tropical rainstorms sweep over the country. If then even a small tank has been neglected, and rats and porcupines have been allowed to burrow in the dam, the flood may burst through it, and sweep on and over the dam of the next village, lower down. One dam may then burst after another, like a pack of cards, and terrible loss occurs.

In this State of Mysore a very remarkable irrigation reservoir is now under construction at a place called Mari Kanave. Nature seems here to have formed an ideal site for a reservoir, so that it is almost irresistible for the engineer to do his part, even although irrigation is not so badly wanted here as elsewhere. The comparatively narrow neck of a valley containing 2075 square miles is being closed by a masonry dam 142 feet high. The reservoir thus formed will contain 30,000 million cubic feet of water, but it is not considered that it will fill more than once in thirty years. Nor is there irrigable land requiring so great a volume of water. Much less would be sufficient, so such a high dam is not needed; but the construction of a waste weir to prevent the submergence of a lower dam would require such heavy excavation through one of the limiting hills that it is cheaper to raise the dam and utilise a natural hollow in the hillside for a waste weir.

Irrigation in Egypt.

No lecture on irrigation would be complete without describing what has been done in Egypt. You are generally familiar with the shape of that famous little country. Egypt proper extends northwards from a point in the Nile about 780 miles above Cairo—a long valley, never eight miles wide, sometimes not half a mile. East and west of this lies a country broken into hills and valleys, wild crags, level stretches, but everywhere absolutely sterile, dry sand and rock, at such a level that the Nile flood has never reached it to cover its nakedness with fertile deposit. A few miles north of Cairo the river bifurcates, and its two branches flow each for about 130 miles to the sea. As you are probably aware, with rivers in a deltaic state the tendency is for the slope of the country to be away from the river, and not towards it. In the Nile Valley the river banks are higher than the more distant lands. From an early period embankments were formed along each side of the river, high enough not to be topped by the highest flood. At right angles to these river embankments others were constructed, dividing the whole valley into a series of oblongs, surrounded on three sides by embankments, on the fourth by the desert heights. These oblong areas vary from about 50,000 to 3000 acres. I have said the slope of the valley is away from the river. It is easy, then, when the Nile is low, to cut short deep canals in the river banks, which fill as the river rises and carry the precious mud-charged water into these great flats. There the water remains for a month or more, some three or four feet deep, depositing its mud, and then at the end of the flood it may either be run off direct into the receding river, or cuts may be made in the cross embankments and the water passed off one flat after another, and finally rejoin the river. This takes place in November, when the river is rapidly falling. Whenever the flats are firm enough to allow a man to walk over them with a pair of bullocks, the mud is roughly turned over with a wooden plough, or even the branch of a tree, and wheat or barley is immediately sown. So soaked is the soil after the flood that the seed germinates, sprouts, and ripens in April without a drop of rain or any more irrigation, except what, perhaps, the owner may give from a shallow well dug in the field. In this manner was Egypt irrigated up to about a century ago. The high river banks which the flood could not cover were irrigated directly from the river, the water being raised as I have already described.

The Barrage.

With the last century, however, appeared a very striking figure in Egyptian history, Muhammed Ali Pasha, who came from Turkey a plain captain of infantry, and before many years had made himself master of the country, yielding only a very nominal respect to his suzerain lord, the Sultan at Constantinople.

Muhammed Ali soon recognised that with this flood system of irrigation only one cereal crop was raised in the year, while with such a climate and such a soil, with a teeming population and with the markets of Europe so near, something far more valuable might be raised. Cotton and sugar-cane would fetch far higher prices; but they could only be grown at a season when the Nile is low, and they must be watered at all seasons. The water-surface at low Nile is about 25 feet below the flood-surface, or more than 20 feet below the level of the country. A canal, then, running 12 feet deep in the flood would have its bed 13 feet above the low-water surface. Muhammed Ali ordered the canals in Lower Egypt to be deepened; but this was an enormous labour, and as they were badly laid out and graded they became full of mud during the flood and required to be dug out afresh. Muhammed Ali was then advised to raise the water-surface by erecting a dam (or, as the French called it, a *barrage*) across the apex of the delta, twelve miles north of Cairo, and the result was a very costly and imposing work, which it took long years and untold wealth to construct, and which was no sooner finished than it was condemned as useless.

Egyptian Irrigation since the English Occupation.

With the English occupation in 1883 came some English engineers from India, who, supported by the strong arm of Lord Cromer, soon changed the situation. The first object of their attention was the *barrage* at the head of the delta, which was made thoroughly sound in six years and capable of holding up 15 feet of water. Three great canals were taken from above it, from which a network of branches are taken, irrigating the province to the left of the western, or Rosetta branch of the river, the two provinces between the branches, and the two to the right of the eastern, or Damietta branch.

In Upper Egypt, with one very important exception (the Ibrahimieh Canal, which is a perennial one), the early flood system of irrigation, yielding one crop a year, prevailed until very recently, but it was immensely improved after the British occupation by the addition of a great number of masonry head sluices, aqueducts, escape weirs, &c., on which some 800,000*l.* was spent. With the completion of these works, and of a complete system of drainage, to be alluded to further on, it may be considered that the irrigation system of Egypt was put on a very satisfactory basis. There was not much more left to do, unless the volume of water at disposal could be increased.

Probably no large river in the world is so regular as the Nile in its periods of low supply and of flood. It rises steadily in June, July, and August. Then it begins to go down, at first rapidly, then slowly, till the following June. It is never a month before its time, never a month behind. It is subject to no exceptional floods from June to June. Where it enters Egypt the difference between maximum and minimum Nile is about 25 feet. If it rises $3\frac{1}{2}$ feet higher the country is in danger of serious flooding. If in former days its rise was 6 feet short of the average there existed a great risk that the floods would not cover the extensive flats of Upper Egypt, and thus the ground would remain as hard as stone, and sowing in November would be impossible. Fortunately the good work of the last twenty years very much diminishes this danger.

The Assuan Dam and Reservoir.

In average years the volume of water flowing past Cairo in September is from thirty-five to forty times the volume in June. By far the greater part of this flood flows out to the sea useless. How to catch and store this supply for use the following May and June was a problem early pressed on the English engineers in Egypt.

During the time of the highest flood the Nile carries along with it an immense amount of alluvial matter, and when it was first proposed to store the flood-water the danger seemed to be that the reservoir would in a few years be filled with deposit, as those I have described in India. Fortunately it was found that after November the water was fairly clear, and that if a commencement were made even as late as that there would still be water enough capable of being stored to do enormous benefit to the irrigation.

A site for a great dam was discovered at Assuan, 600 miles south of Cairo, where a dyke of granite rock crosses the valley of the river, occasioning what is known as the First Cataract. On this ridge of granite a stupendous work has now been created. A great wall of granite 6400 feet long has been thrown across the valley, 23 feet thick at the crest, 82 feet at the base. Its height above the rock-bed of the river is 130 feet. This great wall or dam holds up a depth of 66 feet of water, which forms a lake of more than 100 miles in length up the Nile Valley, containing 38,000 million cubic feet of water.

The dam is pierced with 180 sluices, or openings, through which the whole Nile flood, about 360,000 cubic feet per second, is discharged. A flight of four locks, each 260×30 feet, allows of free navigation past the dam. The foundation-stone of this great work was laid in February 1899, and it was completed in less than four years. At the same time a very important dam of the pattern of the barrage north of Cairo was built across the Nile at Assiut, just below the head of the Ibrahimieh Canal, not with the object of storing water, but to enable a requisite supply at all times to be sent down that canal.

The chief use of the great Assuan reservoir is to enable perennial irrigation, such as exists in Lower Egypt, to be substituted in Upper Egypt for the basin system of watering the land only through the Nile flood; that is, to enable two crops to be grown instead of one every year, and to enable cotton and sugar-cane to take the place of wheat and barley. But a great deal more had to be done in order to obtain the full beneficial result of the work. About 450,000 acres of basin irrigation are now being adapted for perennial irrigation. Many new canals have had to be dug, others to be deepened. Many new masonry works have had to be built. It is probable the works will be finished in 1908. There will then have been spent on the great dam at Assuan, the minor one at Assiut, and the new canals of distribution in Upper Egypt about six and a half millions sterling. For this sum the increase of land rental will be about 2,637,000*l.*, and its sale value will be increased by about 26,570,000*l.*

Drainage.

In the great irrigation systems which I have been describing, for a long time little or no attention was paid to drainage. It was taken for granted that the water would be absorbed or evaporated, and get away somehow without doing any harm. This may hold good for high-lying lands, but alongside of these are low-lying lands into which the irrigation water from above will percolate and produce waterlogging and marsh. Along with the irrigation channel should be constructed the drainage channel, and Sir W. Willcocks, than whom there is no better authority on this subject, recommends that the capacity of the drain should be one-third that of the canal. The two should be kept carefully apart—the canal following the ridges, the drain following the hollows of the country, and one in no case obstructing the other. This subject of drainage early occupied the attention of the English engineers in Egypt. In the last twenty years many hundred miles of drains have been excavated, some as large as 50 feet width of bed and 10 feet deep.

Irrigation in America.

If it is to Italy that we should look for highly finished irrigation works and careful water distribution, and to India and Egypt for widespreading tracts of watered land, it is to America that we naturally look for rapid progress and bold engineering. In the Western States of America there is a rainfall of less than 20 inches per annum, the consequence of which is a very rapid development of irrigation works. In 1889 the irrigation of these Western States amounted to 3,564,416 acres. In 1900 it amounted to 7,539,545 acres. Now it is at least 10,000,000 acres. The land in these States sells from 10*s.* to 1*l.* per acre if unirrigated. With irrigation the same land fetches 8*l.* 10*s.* per acre. The works are often rude and of a temporary nature, the extensive use of timber striking a foreigner from the Old World. Some of the American canals are on a large scale. The Idaho Company's canal discharges 2585 cubic feet, the Turlock Canal in California 1500 cubic feet, and the North Colorado Canal 2400 cubic feet per second. These canals have all been constructed by corporations or societies, in no case by Government. On an average it has cost about 32*s.* per acre to bring the water on to the land, and a water-rate is charged of from 2*l.* 8*s.* to 4*l.* per acre, the farmer paying in addition a rate of from 2*s.* to 10*s.* per acre annually for maintenance. Distributary channels of less than 5 feet wide cost less than 100*l.*, up to 10 feet wide about 150*l.* per mile.

The Introduction of Irrigation into a Country.

It is evident that there are many serious considerations to be taken into account before entering on any large project for irrigation. Statistics must be carefully collected of rainfall, of the sources of water supply available, and of the amount of that rainfall which it is possible to store and utilise. The water should be analysed if there is any danger of its being brackish. Its temperature should be ascertained. It should be considered what will be the effect of pouring water on the soil, for it is not always an unmixed benefit. A dry climate may be changed into a moist, and fever and ague may follow. In India there are large tracts of heavy black soil, which with the ordinary rainfall produce excellent crops nine years out of ten, and where irrigation would rather do harm than good. But in the tenth year the rains fail, and without artificial irrigation the soil will yield nothing. So terrible may be the misery caused by that tenth year of drought that even then it might pay a Government to enter on a scheme of irrigation. But it is evident that it might not pay a joint-stock company.

In all cases it is of the first importance to establish by law the principle that all rivers or streams above a certain size are national property, to be utilised for the good of

the nation. Even where there is no immediate intention of constructing irrigation works it is well to establish this principle. Otherwise vested rights may be allowed to spring up, which it may be necessary in after years to buy out at a heavy cost.

Modes of Distributing and Assessing Water.

Where the river is too inconsiderable to be proclaimed as national property, and where there is no question of spreading the water broadcast over the land, but of bestowing it with minute accuracy over small areas to rear valuable plants, such as fruit-trees, it may be very well left to local societies or to syndicates of farmers to manage their own affairs. Where irrigation is on a larger scale, and its administration is a matter of national importance, the control of the water requires the closest consideration, especially if, as is usually the case, the area which may be irrigated exceeds the volume of water available to irrigate it, and where the water is delivered to the fields by gravitation without the labour of raising it. It must be decided on what principle the farmer's right to the water is to be determined. Is he to obtain water in proportion to the area of his land which is irrigable? If part of the irrigable land is not yet cultivated, is some of the supply to be reserved for such land? Is he to pay in proportion to the area actually watered each crop, or to the area which he might water if he chose? Where the slope of the land is sufficient to allow the water to flow freely out of a sluice into the field channel, it is not difficult to measure the water discharged. Modules have been invented for this purpose, and the owner of the field may be required to pay for so many cubic feet of water delivered. The Government or the association owning the canal will then have nothing to do with the way in which the water is employed, and self-interest will force the farmer to exercise economy in flooding his land. But even then precautions must be taken to prevent him from keeping his sluice open when it should be shut.

In Italy and in America water is generally charged by the module; but in many cases, where the country is very flat, the water cannot fall with a free drop out of the sluice, and, as far as I know, no satisfactory module has yet been invented for delivering a constant discharge through a sluice when the head of water in the channel of supply is subject to variation. These are the conditions prevailing in the plains of Northern India, where there is a yearly area of canal irrigation of about six millions of acres. The cultivator pays not in proportion to the volume of water he uses, but on the area he waters every crop, the rate being higher or lower according as the nature of the crop demands more or less water.

The procedure of charging for water is, then, as follows: When the crop is nearly ripe the canal watchman, with the village accountant and the farmers interested, go over the fields with a Government official. The watchman points out a field which he says has been watered. The accountant, who has a map and field-book of the village, states the number and the area of the field and its cultivator. These are recorded along with the nature of the crop watered. If the cultivator denies that he has received water, evidence is heard and the case is settled. A bill is then made out for each cultivator, and the amount is recovered with the taxes.

This system is perfectly understood, and works fairly well in practice. But it is not a satisfactory one. It holds out no inducement to the cultivator to economise water, and it leaves the door open to a great deal of corruption among the canal watchmen and the subordinate revenue officials.

Government Control of Water Supply.

Where the subject agricultural population is unfitted for representative government it is best that the Government should construct and manage the irrigation, on rules carefully considered and rigorously enforced, through the agency of officers absolutely above suspicion of corruption or unfair dealing. Such is the condition in Egypt and in the British possessions in India. Objections to it are evident enough. Officials are apt to be formal and inelastic, and they are often far removed from any close touch with the cultivating classes. But they are impartial and just, and I know of no other system that has not still greater defects.

Even if the agricultural classes in India were much better educated than they are, it would still be best that the control of the irrigation should rest with the Government. By common consent it is the Government alone that rules the army. Now the irrigation works form a great army, of which the first duty is to fight the grim demon of famine. Their control ought, therefore, to rest with the Government; but the conditions are very different when the agricultural classes are well educated and well fitted to manage their own affairs.

Irrigation is too new and experimental in America for us to look there for a well-devised scheme of water control. The laws and rules on the subject vary in different States, and are often contradictory. It is better to look at the system evolved after long years in North Italy.

The Italian System.

I have already alluded to the great Cavour Canal in Piedmont. This fine work was constructed by a syndicate of English and French capitalists, to whom the Government gave a concession in 1862. Circumstances to which I need not allude ruined this company, and the Government, who already had acquired possession of many other irrigation works in Piedmont, took over the whole Cavour Canal in 1874, a property valued at above four millions sterling, and ever since the Government has administered it.

The chief interest of this administration centres on the Irrigation Association West of the Sesia,[1] an association that owes its existence to the great Count Cavour. It takes over from the Government the control of all the irrigation effected by the Cavour and other minor canals within a great triangle lying between the left bank of the Po and the right bank of the Sesia. The association purchases from the Government from 1250 to 1300 cubic feet per second. In addition to this it has the control of all the water belonging to private canals and private rights, which it purchases at a fixed rate. Altogether it distributes about 2275 cubic feet per second, and irrigates therewith about 141,000 acres, of which rice is the most important crop. The association has 14,000 members, and controls 9600 miles of distributary channels. In each parish is a council, or, as it is called, a *consorzio*, composed of all landowners who take water. Each *consorzio* elects one or two deputies, who form a sort of water-parliament. The deputies are elected for three years, and receive no salary. The assembly of deputies elects three committees—the direction-general, the committee of surveillance, and the council of arbitration. The first of these committees has to direct the whole distribution of the waters, to see to the conduct of the *employés*, &c. The committee of surveillance has to see that the direction-general does its duty. The council of arbitration, which consists of three members, has most important duties. To it may be referred every question connected with water-rates, all disputes between members of the association or between the association and its servants, all cases of breaches of rule or of discipline. It may punish by fines any member of the association found at fault, and the sentences it imposes are recognised as obligatory, and the offender's property may be sold up to carry them into effect. An appeal may be made within fifteen days from the decisions of this council of arbitration to the ordinary law courts, but so popular is the council that, as a matter of fact, such appeals are never made.

To effect the distribution of the water the area irrigated is divided into districts, in each of which there is an overseer in charge and a staff of guards to see to the opening and closing of the modules which deliver the water into the minor watercourses. In the November of each year each parish sends in to the direction-general an indent of the number of acres of each description of

1 See Mr. Elwood Mead's "Report on Irrigation in Northern Italy," Printed for the Department of Agriculture, Washington, 1904.

crop proposed to be watered in the following year. If the water is available the direction-general allots to each parish the number of modules necessary for this irrigation; but it may quite well happen that the parish may demand more than can be supplied, and may have to substitute a crop like wheat, requiring little water, for rice, which requires a great deal.

The Government executes and pays for all repairs on the main canals. It further executes, at the cost of the Irrigation Association, all repairs on the minor canals. The association, then, has no engineers in its employ, but a large staff of irrigators. The irrigation module employed in Piedmont is supposed to deliver 2·047 cubic feet per second. The Association West of the Sesia buys from the Government what water it requires at a rate fixed at 800 liras per module, or 15*l.* 12*s.* 7*d.* per cubic foot per second per annum.

The association distributes the water by module to each district, and the district by module to each parish. Inside the parish each farmer pays, according to the area he waters, a sum to cover all the cost of the maintenance of the irrigation system, and his share of the sum which the association has to pay to the Government. This sum varies from year to year according as the working expenses of the year increase or diminish.

I have already mentioned the recently constructed Villoresi Canal in Lombardy. This canal belongs to a company, to whom the Government has given large concessions. This company sells its water wholesale to four districts, each having its own secondary canal, the cubic metre per second, or 35·31 cubic feet per second, being the unit employed. These districts, again, retail the water to groups of farmers termed *comizios,* whose lands are watered by the same distributary channels, their unit being the litre, or 0·035 cubic foot, per second. Within the *comizio* the farmer pays according to the number of hours per week that he has had the full discharge of the module.

I have thought it worth while to describe at some length the systems employed on these Italian canals, for the Italian farmers set a very high example, in the loyal way in which they submit to regulations which there must at times be a great temptation to break. A sluice surreptitiously opened during a dark night, and allowed to run for six hours, may quite possibly double the value of the crop which it waters. It is not an easy matter to distribute water fairly and justly between a number of farms at different levels, dependent on different watercourses, cultivating different crops. But in Piedmont this is done with such success that an appeal from the council of arbitration to the ordinary law courts is unheard of. It is thought apparently as discreditable to appropriate an unfair supply of water as to steal a neighbour's horse, as discreditable to tamper with the lock of the water module as with the lock of a neighbour's barn.

Mr. Schuyler's Views as to Government Control.

Where such a high spirit of honour prevails I do not see why syndicates of farmers should not construct and maintain a good system of irrigation. Nevertheless, I believe it is better that Government should take the initiative in laying out and constructing the canals and secondary channels at least. A recent American author, Mr. James Dix Schuyler, has put on record: "That storage reservoirs are a necessary and indispensable adjunct to irrigation development, as well as to the utilisation of power, requires no argument to prove. That they will become more and more necessary to our Western civilisation is equally sure and certain; but the signs of the times seem to point to the inevitable necessity of Governmental control in their construction, ownership, and administration."

This opinion should not be disregarded. Sir W. Willcocks has truly remarked: "If private enterprise cannot succeed in irrigation works of magnitude in America, it will surely not succeed in any other country in this world." What its chances may be in South Africa I leave to my hearers to say. It is not a subject on which a stranger can form an opinion.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY A. C. HADDON, Sc.D., F.R.S., PRESIDENT OF THE SECTION.

THERE are various ways in which man can study himself, and it is clearly impossible for me to attempt to give an exposition of all the aims and methods of the anthropological sciences; I propose, therefore, to limit myself to a general view of South African ethnology, incidentally referring to a few of the problems that strike a European observer as needing further elucidation. It seems somewhat presumptuous in one who is now for the first time visiting this continent to venture to address a South African audience on local ethnology, but I share this disability with practically all students of anthropology at home, and my excuse lies in the desire that I may be able to point out to you some of the directions in which the information of anthropologists is deficient, with the hope that this may be remedied in the immediate future.

Men are naturally apt to take an exclusive interest in their immediate concerns, and even anthropologists are liable to fall into the danger of studying men's thoughts and deeds by themselves, without taking sufficient account of the outside influences that affect mankind.

In the sister science of zoology, it is possible to study animals as machines which are either at rest or in motion: when they are thus studied individually, the subjects are termed anatomy and physiology; when they are studied comparatively, they are known as comparative anatomy or morphology and comparative physiology. The study of the genesis of the machine is embryology, and palæontologists, as it were, turn over the scrap-heap. All these sciences can deal with animals irrespective of their environment, and perhaps for intensive study such a limitation is temporarily desirable, but during the period of greatest specialisation there have always been some who have followed in the footsteps of the field naturalist, and to-day we are witnessing a combination of the two lines of study.

Biology has ceased to be a mixture of necrology and physiology; it seeks to obtain a survey of all the conditions of existence, and to trace the effects of the environment on the organism, of the organism on the environment, and of organism upon organism. Much detailed work will always be necessary, and we shall never be able to do without isolated laboratory work; but the day is past when the amassing of detailed information will satisfy the demands of science. The leaders, at all events, will view the subject as a whole, and so direct individual labour that the hewers of wood and drawers of water, as it were, shall not mechanically amass material of which no immediate use can be made, but they will be so directed that all their energies can be exercised in solving definite problems or in filling up gaps in our information, with knowledge which is of real importance.

This tendency, which I have indicated as affecting the science of zoology, is merely one phase of an attitude of mind that is influencing many departments of thought. There are psychologists and theologians who deem it worth while to find out what other people think and believe. Arm-chair philosophers are awakening to the fact that their studies have hitherto been confined almost exclusively to the most highly specialised conditions, and that in order to comprehend these fully it is necessary to study the less and the yet less specialised conditions; for it is only possible to gain the true history of mind or belief by a combination of the observational with the comparative method. A considerable amount of information has already been acquired, but in most departments of human thought and belief vastly more information is needed, and hitherto the trustworthiness of a great deal that has been published is not above suspicion.

The comparative or evolutionary historian also needs trustworthy facts concerning the social condition of varied peoples in all stages of culture. The documentary records of history are too imperfect to enable the whole story to be unravelled, so recourse must be had to a study of analogous conditions elsewhere for side-lights which will cast illuminating beams into the dark corners of ancient history. When the historian seriously turns his attention

to the mass of data accumulated in books of travel, in records of expeditions, or the assorted material in the memoirs of students, he will doubtless be surprised to find how much there is that will be of service to him.

Sociologists have not neglected this field, but they need more information and more exhaustive and precise analyses of existing conditions. The available material is of such importance and interest, that the pleasure of the reader is apt to dull his critical faculty; as a matter of fact, the social conditions of extremely few peoples are accurately known, and sooner or later—generally sooner—the student finds his authorities failing him from lack of thoroughness.

I have alluded to the subjects of psychology, theology, history, and sociology, because they all overlap that area over which the anthropologist prowls. Indeed it is our work to collect, sift, and arrange the facts which may be utilised by our colleagues in these other branches of inquiry, and to this extent the ethnologist is also a psychologist, a theologian, a historian, and a sociologist.

Similarly the anthropographer provides material for the biologist on the one hand, and for the geographer on the other.

As a general rule those who have investigated any given people in the field have alluded to the general features of the country they inhabit, so that usually it is possible to gain some conception of them in their natural surroundings. Thus, to a certain extent, materials are available for tracing that interaction between life and environment and between organisms themselves, to which the term Œcology is now frequently applied, but we still need to have this interdependence more recognised in such branches of inquiry as descriptive sociology or religion.

Just as the arts and crafts of a people are influenced by their environment, so is their social life similarly affected, and their religion reflects the stage of social culture to which they have attained; for it must never be overlooked that the religious conceptions of a people cannot be thoroughly understood apart from their social, cultural, and physical conditions.

This may appear a trite remark, but I would like to emphasise the fact that very careful and detailed studies of definite or limited areas are urgently needed, rather than a general description of a number of peoples which does not exhaust any one of them—in a word, what we now need is thoroughness.

Three main groups of indigenous peoples inhabit South Africa—the Bushmen, the Hottentots, and various Bantu tribes; in more northerly parts of the continent there are the Negrilloes, commonly spoken of as Pygmies, the Negroes proper, and Hamitic peoples, not to speak of Arab and Semitic elements.

Kattea.

Before proceeding further I must here make allusion to an obscure race who may possibly be the true aborigines of Africa south of the Zambesi. These are the Kattea—or Vaalpens, as they are nicknamed by the Boers, on account of the dusty colour their abdomen acquires from the habit of creeping into their holes in the ground—who live in the steppe region of the North Transvaal, as far as the Limpopo. As their complexion is almost a pitch-black, and their stature only about 1·220 m. (4 ft.), they are quite distinct from their tall Bantu neighbours and from the yellowish Bushmen. The "Dogs," or "Vultures," as the Zulus call them, are the "lowest of the low," being undoubtedly cannibals and often making a meal of their own aged and infirm, which the Bushmen never do. Their habitations are holes in the ground, rock shelters, and lately a few hovels. They have no arts or industries, nor even any weapons except those obtained in exchange for ostrich feathers, skins, or ivory. Whether they have any religious ideas it is impossible to say, all intercourse being restricted to barter carried on in a gesture language, for nobody has ever yet mastered their tongue, all that is known of their language being that it is absolutely distinct from that of both the Bushman and the Bantu. There are no tribes, merely little family groups of from thirty to fifty individuals, each of which is presided over by a headman, whose functions are acquired, not by heredity, but by personal qualities. I have compiled this account of this most interesting people from Prof. A. H. Keane's book, "The Boer States," in the hope that a serious effort will be made to investigate what appears to be the most primitive race of all mankind. So little information is available concerning the Kattea that it is impossible to say anything about their racial affinities.

Perhaps these are the people referred to by Stow (p. 40), and possibly allied to these are the dwarfs on the Nosop River mentioned by Anderson; these were 1·125 m. (4 ft. 4 in.) or less in height, of a reddish-brown colour, with no forehead and a projecting mouth; Anderson's Masara Bushmen repudiated any suggestion of relationship with them, saying they were "monkeys, not men."

Bushmen.

The San, or Bushmen (Bosjesman of colonial annals), may, with the possible exception of the Kattea, be regarded as the most primitive of the present inhabitants of South Africa; according to most authors, there is no decisive evidence that there was an earlier aboriginal population, although M. G. Bertin informs us that Bushman tales always speak of previous inhabitants.

The main physical characteristics of the Bushmen are a yellow skin, and very short, black, woolly hair, which becomes rolled up into little knots; although of quite short stature, with an average height of 1·529 m. (5 ft. 0¼ in.), or, according to Schinz, 1·570 m. (5 ft. 1⅘ in.), they are above the pygmy limit of 1·450 m. (4 ft. 9 in.). The very small skull is not particularly narrow, being what is termed sub-dolichocephalic, with an index of about 75, and it is markedly low in the crown; the face is straight, with prominent cheekbones and a bulging forehead; the nose is extremely broad—indeed, the Bushmen are the most platyrrhine of all mankind; the ear has an unusual form, and is without the lobe. Their hands and feet are remarkably small.

Being nomadic hunters the Bushmen could only attain to the rudiments of material culture. The dwellings were portable, mat-covered, dome-shaped huts, but they often lived in caves; the Zulus say "their village is where they kill game; they consume the whole of it and go away." Clothing consisted solely of a small skin; for weapons they had small bows and poisoned arrows. Their only implement was a perforated rounded stone into which a stick was inserted; this was used for digging up roots. A very little coarse pottery was occasionally made. Although with a great dearth of personal ornaments, they had a fair amount of pictorial skill, and were fond of decorating their rock shelters with spirited coloured representations of men and animals. They frequently cut off the terminal joint of a little finger. They never were cannibals. Cairns of stones were erected over graves. Although they are generally credited with being vindictive, passionate, and cruel, they were as a matter of fact always friendly and hospitable to strangers until dispossessed of their hunting grounds. They did not fight one another, but were an unselfish, merry, cheerful race with an intense love of freedom.

A great mass of unworked material exists for the elucidation of the religious ideas, legends, customs, and so forth, of the Bushmen, in the voluminous native texts, filling eighty-four volumes, to the collection of which the late Dr. Bleek devoted his laborious life. This wonderful collection of the folklore of one of the most interesting of peoples still remains inaccessible to students in the Grey Library in Cape Town. A more enlightened policy in the past would have enabled Dr. Bleek to publish his own material; now the task is complicated by the great difficulty of finding competent translators and of securing the services of trustworthy natives who know their own folklore. The time during which this labour can be adequately accomplished is fleeting rapidly, and once more the Government must be urged to complete and publish the life-work of this devoted scholar.

The Mañanja natives, who live south of Lake Shirwa, assert that formerly there lived on the upper plateau of the mountain mass of Mlanje a people they call Arungu, or "gods," who from their description must have been Bushmen. Relics of Bushman occupation have been found in the neighbourhood of Lakes Nyassa and Tanganyika.

West of the Arangi plateau in German East Africa, between the steppes occupied by the Wanyamwezi and the Masai, live the Wasandawi, a settled hunting people who, according to Baumann, are very different from the surrounding Bantu peoples, and who are allied to the more primitive, wandering, hunting Wanege, or Watindiga, of the steppes near Usukuma. They use the bow and poisoned arrow. Their language, radically distinct from Bantu, is full of those strange click sounds which are characteristic of Bushman speech; but Sir Harry Johnston says that he does not know if any actual relationship has been pointed out in the vocabulary, and he distinctly states that the Sandawi are not particularly like the Bushmen in their physique, but more resemble the Nandi; and Virchow declares there is no relationship between the Wasandawi and the Hottentot in skull-form. Until further evidence is collected, one can only say that there may have been a Bushman people here who have become greatly modified by intermixture with other races. Sir Harry Johnston thinks that possibly traces of these people still exist among the flat-faced, dwarfish Doko, who live to the north of Lake Stephanie, and he is inclined to think that traces of them occur also among the Andorobo and Elgunono.

If the foregoing evidence should prove to be trustworthy, it would seem that at a very early time the Bushmen occupied the hunting grounds of tropical East Africa, perhaps even to the confines of Abyssinia. They gradually passed southwards, keeping along the more open grass lands of the eastern mountainous zone, where they could still preserve their hunting method of life, until, at the dawn of history, they roamed over all the territory south of the Zambesi, with the exception of the eastern seaboard.

Negrilloes.

Material does not at present exist for an exhaustive discussion of the exact relationship between the Bushmen and the Negrilloes of the Equatorial forests. On the whole I am inclined to agree with Sir Harry Johnston, who says: "I can see no physical features other than dwarfishness which are obviously peculiar to both Bushmen and Congo Pygmies. On the contrary, in the large and often protuberant eyes, the broad flat nose with its exaggerated alæ, the long upper lip and but slight degree of eversion of the inner mucous surface of the lips, the abundant hair on head and body, relative absence of wrinkles, of steatopygy, and of high protruding cheekbones, the Congo dwarf differs markedly from the Hottentot-Bushman type." Shrubsall had previously stated: "For the present I can only say that the data seem to me too insufficient to enable the affinities of the various pygmy races to be clearly demonstrated, or to allow of much significance being attached to any apparent resemblance." Deniker also directs attention to the physical characters that distinguish those two types, and he concludes that "nothing justifies their unification."

Hottentots.

The skin of the Hottentots, or Khoikhoi, as they style themselves, is of a brownish-yellow, with a tinge of grey, sometimes of red; the hair is very similar to that of the Bushmen; the average stature is 1·604 m. (5 ft. 3 in.); the head is small and distinctly dolichocephalic (74), the jaws prognathic, cheekbones prominent, and chin small. Shrubsall, who has investigated the osteological evidence, says no hard-and-fast line can be drawn from craniological evidence between Hottentots and Bushmen on the one hand and Negroid races on the other, various transitional forms being found; but Bushman characteristics undoubtedly predominate in the true Hottentots.

The Hottentots were grouped in clans, each with its hereditary chief, whose authority, however, was very limited. Several clans were loosely united to form tribes. Their principal property consisted of horned cattle and sheep; the former were very skilfully trained. The dwellings were portable, mat-covered, dome-shaped huts. For weapons they had a feeble bow with poisoned arrows, but they also had assegais and knobkerries or clubbed sticks used as missiles; coarse pottery was made. They were often described as mild and amiable.

The Hottentot migration from the eastern mountainous zone took place very much later than that of the Bushmen, and it seems to have been due mainly to the pressure from behind of the waxing Bantu peoples. These pastoral nomads took a south-westerly course across the savanna country, and if the tsetse fly had the same distribution then as now they probably, more or less, followed the right bank of the Zambesi, then struck across to the Kunene north of the desert land, and worked their way down the west coast and along the southern shore of the continent.

What is now Cape Colony was inhabited solely by Bushmen and Hottentots at the time of the arrival of the Europeans. As the latter expanded they drove the aborigines before them, but in the meantime mongrel peoples had arisen, mainly of Boer-Hottentot parentage, who also were forced to migrate. Those of the Cape Hottentots who were not exterminated or enslaved drifted north and found in Bushman Land an asylum from their pursuers. The north-east division of the Hottentots comprises the Koranna, or Goraqua; they were an important people, despite the fact that they had no permanent home. They migrated along the Orange River—one section went up the right bank of the Harts and the other went up the Vaal until they were deflected by the Bechuana. When the Boers in 1858 were engaged with the Basuto, the Koranna devastated the Orange Free State, but were themselves ultimately destroyed. The original home of the Griqua was in the neighbourhood of the Olifant River; in the middle of the eighteenth century the colonists settled in the land, and as a result the Griqua-Bastards retreated to the east under the leadership of the talented Adam and Cornelius Kok. They adopted the name Griqua in place of the earlier one of Bastard; one split founded Griqua Town in Griqualand West, but the other went further east and eventually settled east of the Drakensberg, between Natal and Basutoland, and occupied the country devastated by Chaka's wars. Here rose the chief town, Kokstadt, in Griqualand East, where a few Griqua still live. The interesting little nation of the Bastards, descendants of unions between Europeans, mostly Boers, and Hottentot women, now mixes very little with other peoples. They were forced in 1868 to leave their home in Great Bushmanland owing to the ravages of Bushmen and Koranna, and finally, after various wanderings and vicissitudes, they settled as four communities in Great Namaqualand, in German territory. Namaqualand is too infertile to attract colonists, and thus it forms an asylum for expatriated Hottentots as well as for the Namaqua division of the Hottentots, the original inhabitants of the country.

True Negroes.

One of the most primitive populations of Africa is that of the true, or West Africa, Negroes. At present this element is mainly confined to the Sudan and the Guinea Coast.

The main physical characteristics of the true Negro are: "black" skin, woolly hair, tall stature, averaging about 1·730 m. (5 ft. 8 in.), moderate dolichocephaly, with an average cephalic index of 74–75. Flat, broad nose, thick and often everted lips, frequent prognathism.

West African culture contains some characteristic features. The natives build gable-roofed huts; their weapons include spears with socketed heads, bows tapering at each end with bowstrings of vegetable products, swords and plaited shields, but no clubs or slings. Among the musical instruments are wooden drums and a peculiar form of guitar, in which each string has its own support. Clothing is of bark-cloth and palm-fibre, and there is a notable preponderance of vegetable ornaments. Circumcision is common and the knocking out of the upper incisors. With regard to religion, there is a great development of fetishism and incipient polytheistic systems. Colonel Ellis has proved in a masterly manner the gradual evolution of religion from west to east along the Guinea Coast, and this is associated with an analogous progress in the laws of descent and succession to property, and in the rise of government. He further suggests that differences in the physical character of each country in question have played a great part in this progressive evolution. Here also are to be found secret societies, masks and representations of human figures. The ordeal by poison is employed, chiefly for the discovery of witchcraft; anthro-

pophagy occurs. The domestic animals are the dog, goat, pig, and hen. Cattle are absent owing to the tsetse fly. The plants originally cultivated were beans, gourds, bananas, and perhaps earth-nuts. Coiled basketry and head-rests are absent.

That branch of the true Negro stock which spake the mother-tongue of the Bantu languages some 3000 years ago (according to Sir Harry Johnston's estimate) spread over the area of what is now Uganda and British East Africa. In the Nile valley these people probably mixed with Negrilloes, and possibly with the most northerly representatives of the Bushmen in the high lands to the east. Here also they came into contact with Hamitic peoples coming down from the north, and their amalgamation constituted a new breed of Negro—the Bantu. We have already seen what are some of the more important physical characteristics of the Negro, Negrillo, and Bushman stocks; it only remains to note in what particulars they were modified by the new blood.

Hamites.

The Hamites are to be regarded as the true indigenous element in North Africa, from Morocco to Somaliland. Two main divisions of this stock are generally recognised: (1) the Northern or Western Hamites (or Mediterranean race of some authors), of which the purest examples are perhaps to be found among the Berbers; and (2) the Eastern Hamites or Ethiopians. These two groups shade into each other, and everywhere a Negro admixture has taken place to a variable extent since very early times. The Hamites are characterised by a skin-colour that varies considerably, being white in the west and various shades of coffee-brown, red-brown, or chocolate in the east; the hair is naturally straight or curly, but usually frizzly in the east. The stature is medium or tall, averaging about 1·670 m. (5 ft. 5¾ in.) to about 1·708 m. (5 ft. 7¼ in.); the head is sub-dolichocephalic (75–78); the face is elongated and the profile not prognathous; the nose prominent, thin, straight or aquiline, with narrow nostrils; lips thin or slightly tumid, never everted.

Bantu.

Roughly speaking, the whole of Africa south of the equator, with the exception of the dwindling Bushman and Hottentot elements, is inhabited by Bantu-speaking peoples, who are extremely heterogeneous, but who exhibit sufficient similarities in physical and cultural characteristics to warrant their being grouped together: the true Negro may be regarded as a race; the Bantu are mixed peoples.

It will be noticed that as a rule the Bantu approach the Hamites in those physical characters in which they differ from the true Negroes, and owing to the fact that the physical characters of Semites in the main resemble those of Hamites, any Semitic mixture that may have taken place will tend in the same direction as that of the Hamitic. The diversity in the physical characters of the Bantu is due to the different proportions of mixture of all the races of Africa. What we now require is a thorough investigation of these several elements in as pure a state as possible, and then by studying the various main groups of Bantu peoples their relative amount of racial mixture can be determined.

The physical characteristics of the Bantu vary very considerably. The skin colour is said to range from yellowish-brown to dull slatey-brown, a dark chocolate colour being the prevalent hue. The character of the hair calls for no special remark, as it is so uniformly of the ordinary Negro type. The stature ranges from an average of about 1·640 m. (5 ft. 4½ in.) to about 1·715 m. (5 ft. 7½ in.). Uniformity rather than diversity of head-form would seem to be the great characteristic of the African black races, but a broad-headed element makes itself felt in the population of the forest zone and of some of the upper waters of the Nile Valley. It appears that the broadening of the head is due to mixture with the brachycephalic Negrillo stock, for, whereas the dolichocephals are mainly of tall stature, some of the brachycephals, especially the Aduma of the Ogowe, with a cephalic index of 80·8, are quite short, 1·594 m. (5 ft. 2¾ in.). The character of the nose is often very useful in discriminating between races in a mixed population, but it has not yet been sufficiently studied in Africa, where it will probably prove of considerable value, especially in the determination of the amount of Hamitic or Semitic blood. The results already obtained in Uganda are most promising. Steatopygy is not notable among men; fatty deposits are well developed among women, but nothing approaching the extent characteristic of the Hottentots and Bushmen.

It appears that the Bantu peoples may be roughly divided according to culture into two groups: a western zone, which skirts the West African region and extends through Angola and German West Africa into Cape Colony; and an eastern zone. (1) The western Bantu zone is characterised by beehive huts, the absence of circumcision, and the presence of wooden shields (plain or covered with cane-work) in its northern portion, though skin shields occur to the south. (2) In the eastern Bantu zone the huts are cylindrical, with a separate conical roof.

Certain characteristics are typical of the Bantu culture. The natives live in rounded huts with pointed roofs; their weapons comprise spears, in which the head is fastened into the shaft by a spike, bows of equal thickness along their length, with bowstrings of animal products, clubs and skin shields, but slings are usually absent; the clothing is of skin and leather, and there is a predominance of animal ornaments; knocking out the lower incisors is general, circumcision is common, though among the Kafir tribes it seems to be dying out; ancestor-worship is the prevalent form of religion, fetishism and polytheism are undeveloped; masks and representations of human figures are rare, and there are no secret societies; anthropophagy is sporadic and usually temporary; the domestic animals include the dog, goat, and sheep, and cattle are found wherever possible; coiled basketry is made, and head-rests are a characteristic feature.

M. A. de Préville has drawn a broad line of distinction between the religion of the pastoral Bantu tribes and that of the hunters of the forest belt. The cattle-raisers of the small pastures recognise that the rain and necessary moisture depend on an invisible and supreme power whom they invoke in his location in the sky. His intermediaries are the rain-makers, he has no human form, neither are there idols in the pantheon. In Central Africa there is more than sufficient rain, but rain is of little importance to the hunter. What he requires is to find game, to be able to capture it and to avoid danger; the "medicine-men" are not rain-makers, but makers of talismans, amulets, philtres, and charms to attract the game and to ensure its capture. The mysterious depths of the forest, in the impenetrable thickets of which death may lurk at each step, and the isolation which results in social disorganisation, incline the hunter to superstitious terrors. Pasturage is governed by natural impersonal forces, but hunting is individual and personal. Further, associated with the mobile pastoral life of the Bantu is the patriarchal system of family life, respect and veneration for old age, and the autocracy of the chief; no wonder, then, that ancestor-worship has developed, or that it is the chief factor in the religious life of these people.

As I have previously indicated, there is evidence of the former extension to the north of the Hottentots and the Bushmen, they having gradually been pressed first southwards and then into the steppes and deserts of South Africa by the southerly drifting of the Bantu.

The mixture of Hamite with Negro, which gave rise to the primitive Bantu stock, may have originated somewhere to the east or north-east of the Victoria Nyanza. A factor of great importance in the evolution of the Bantu is to be found in the great diversity of climate and soil in Equatorial East Africa. It is a country of small plateaux separated by gorges, or low-lying lands. The small plateaux are suitable for pasturage, but their extent is limited; thus they fell to the lot of the more vigorous people, while the conquered had to content themselves with low country, and were obliged to hunt or cultivate the land. In these healthy highlands the people multiplied, and migration became necessary; the stronger and better-organised groups retained their flocks and migrated in a southerly direction, keeping to the savannas and open country, the line of least resistance being indicated by the relative social feebleness of the peoples to the south. In the small plateaux a nomadic life is impossible for the

herders: there being at most a seasonal change of pasturage, this prevents the possession of large herds and necessitates a certain amount of tillage; further, it would seem that this mode of life tends to develop military organisation and a tribal system.

No materials at present exist for any attempt at a history of this stage of the Bantu expansion, but from what we know of the great folk-wanderings in South Africa during the first half of the nineteenth century, we can form some estimate of what may have happened earlier in Equatorial Africa.

Lichtenstein lived among the Bechuanas in 1805, and from that date begins our knowledge of the Bantu peoples. Dr. G. M. Theal, the learned historian of South Africa, Dr. K. Barthel and Mr. G. W. Stow, whose valuable book has just appeared, have made most careful studies of folk-wanderings in South Africa, based upon the records of the explorers of the past hundred years; we scarcely have trustworthy accounts of the movements of the various tribes for a longer period, and oral traditions of the natives, though in the main correct, require careful handling. The nature of the country is such that it affords more than ordinary facilities for migrations, and the absence of great geographical barriers prevents ethnical differentiation.

The Bantu peoples of Southern Africa may conveniently be classified in three main groups:—

(1) The eastern tribes, composed of the Zulu-Xosa.

(2) The interior tribes, consisting of the Bechuana, Basuto, Mashona, &c.

(3) The western tribes, such as the Ovampo and Ovaherero.

(1) The Zulu-Xosa are respectively the northern and southern branches of a migration down the east coast, that, according to some authorities, took place about the fifteenth century. The Amaxosa (Kosa, or Kafirs) never overstepped the Drakensberg range, but there have been northerly and, more especially, southerly movements: the Amaxosa, for example, extended, about 1800, as far as Kaaimans River, Mossel Bay, but in 1835 they were pressed back by the colonists to the Great Fish River.

The Amazulu have occupied the east coast, north of the Tugela, for a long period, and allied tribes extend as far as the Zambesi; indeed, it may be said that a complete chain of Zulu peoples stretches up to the neighbourhood of the equator, the more open country in which they live giving greater opportunities for expansion. The wonderful rise to power of Chaka (1783–1828) caused great movements of peoples to take place. The Amangwane (who drove the Amahlubi before them) and other groups fled southward to escape from the tyranny of this great warrior. The conquerors applied to these scattered remnants of tribes the contemptuous term "Fingu," or homeless fugitives, and turned them into slaves and cattle-tenders. The Matabele, to the number of some 60,000 individuals, separated from the parent stock about 1817, under the leadership of the terrible Moselekatze (Umsilikatzi), whose fame as an exterminator of men ranks second only to that of Chaka; they crossed the Drakensberg and went north-west through the Transvaal, scattering the settled Bechuana peoples. They were attacked by the Boers, who defeated them with terrible slaughter, from which only forty warriors escaped. They withdrew to the Zambesi, but were driven south by the tsetse fly. They encountered the Makalaka and destroyed their villages, drove out the Mashona to the north-east, and settled in Mashonaland.

(2) The great central region of the South African plateau, roughly known as Bechuanaland, was very early occupied by Bantu peoples coming from the north, who displaced or reduced to servitude the indigenous Bushmen. As Prof. Keane points out, the Bechuana must have crossed the Zambesi from the north at a very early date, because of all the south Bantu groups they alone have preserved the totemic system. Among the first to arrive, according to him, appear to have been the industrious Mashona and Makalaka. For three hundred years, according to native tradition, the Makalaka owned the land between the Limpopo and the Zambesi, and then came the Barotse, who are allied to the Congo Bantu, and conquered them. A section of the latter founded a powerful so-called Barotse (Marotse) empire on the Middle Zambesi above the Victoria Falls. At the beginning of the nineteenth century a Bahurutse dynasty ruled over the Bechuana; as these people expanded they broke off into clans, and extended between the Orange River and the Zambesi, and from the Kathlamba, or Drakensberg chain, to the Kalahari Desert.

The densely populated country west of the Drakensberg now known as Basutoland was subjected to great devastation as a result of Chaka's tyranny. In 1822 a tribe fleeing from the Zulus set up the first of these disturbances, and the attacked became the attackers in their turn. One horde, the Mantati, achieved great notoriety, and are credited with having wiped out twenty-eight tribes; they were eventually defeated by the Bangwaketsi and scattered by the Griqua. The Makololo, a small group of the Mantati (who lived on the upper waters of the Orange River), led by Sebituane, in 1823 aimed at reaching the district of the Chobe and Zambesi, where he had heard that it was always spring. After conquering the Bakwena, Bahurutse, and other kindred tribes and increasing their forces from the conquered peoples, they crossed the Zambesi and the uplands stretching to the Kafukwe, and settled in those fertile pasture lands about 1835. Disturbed by the Matabele, Sebituane passed through the Barotse Valley, followed by the Matabele and the Batoka, a tribe of the Barotse. He put the former to flight and subjugated the latter. Thus Sebituane led his people a journey of more than 2000 miles to reach their Promised Land. Under Sekeletu, Sebituane's successor, the State began to fall to pieces, and after his death the Barotse revolted, and practically exterminated the Makololo. The rehabilitated Barotse empire comprises an area of some 250,000 square miles between the Chobe and Kafukwe affluents of the Zambesi. Prof. Keane directs attention to the instructive fact that though the Makololo have perished from among the number of South African tribes, their short rule (1835–1870) was long enough to impose their language upon the Barotse, and to this day, about the Middle Zambesi, where the Makololo have disappeared, their speech remains the common medium of intercourse throughout the Barotse empire. The consolidation of the Basuto under the astute Moshesh is an instructive episode in the history of the South African races. The Bamangwato are the most important branch of the independent Bechuana peoples, who have made considerable progress under the wise guidance of the enlightened Khama; they are an industrious people, and have exceptional skill in working iron.

According to Mr. G. W. Stow there were three main migrations of the interior, or middle, Bantu, or Bachoana as he terms them: (i.) The pioneer tribes of the southward migration into the ancient Bushman hunting grounds were the Leghoya, Bakalahari, and those who intermarried with the Bushmen to form the Balala and Bachoana Bushmen; (ii.) the tribes of the second period of the Bachoana migration were the Batlapin and Barolong; (iii.) the great Bakuena or Bakone tribes were the most civilised of the Bantu peoples: they consisted of the Bahurutse, Batlaru, Bamangwato, Batauana, Bangwaketse, and the Bakuena, who were the wealthiest and most advanced of all until they were reduced by the Mantati and destroyed by the Matabele.

(3) Turning for a moment to German South-West Africa we find the Bastards to the south, and north of them the Haukoin or Mountain Damara, who are now practically a pariah people, subject to the Hottentots, Bastards, Ovaherero, and the white man. It is possible that these are of Negro rather than of Bantu origin; in mode of life, save for their talent for agriculture, they are Bushmen; in their speech they are Hottentots, but their colour is darker than that of their neighbours. Somewhere from Eastern South Africa, about a hundred years ago, came the Ovaherero, or the Merry People, who, like the rest of the Bantu, are warlike cattle-breeders, with wandering proclivities, but they are not agriculturists. When they arrived in the Kaoko district they drove the Haukoin to the south, together with the Toppnaers (Aunin) and Bushmen. To the north of the Ovaherero are the agricultural Ovampo.

Speaking generally, the direction of ethnic migration in South Africa has been southerly in the south-east: the sea blocked an eastern expansion and the Drakensberg a western; only the Matabele went westward of this range to the north. In the central district the Bahurutse or Bechuana parent stock dispersed in various directions; most of the movements were towards the north, but the Mantati and Basuto went south-east. In the west the Cape Hottentots always retreated from the colonists towards the north; the Bastards and other tribes followed the same direction, the causes, as Barthel points out, being obvious: to the east is the Kalahari, on the west is the sea, from the south came the pressure of the Boers. Finally, right across South Africa we have, from west to east, the Koranna, Griqua, and Boer wanderings in the south; and in the north, from east to west, the wanderings of the Hottentots, Ovaherero, and of the Boer emigrants from the Transvaal.

South Africa has thus been a whirlpool of moving humanity. In this brief summary I have been able to indicate only the main streams of movement: there have been innumerable cross-currents which add complexity to this bewildering history, and much patient work is necessary before all these complications can be unravelled and their meaning explained.

When one takes a bird's-eye view of the ethnology of South Africa, certain main sociological facts loom out amongst all the wealth of varied detail.

The earliest inhabitants of whom we have any definite information were the dwarf Bushmen, who undoubtedly represent a primitive variety of mankind. In a land abounding with game they devoted themselves entirely to the chase, supplementing their diet with fruit and roots. This mode of life necessitates nomadic habits, the absence of property entails the impossibility of gaining wealth, and thereby relieving part of the population from the daily need of procuring food; this absence of leisure precludes the elaboration of the arts of life. A common effect of the nomadic hunting life is the breaking-up of the community into small groups; the boys can soon catch their own game, hence individualism triumphs and parental authority is apt to be limited. Social control is likely to be feeble unless the religious sentiment is developed, and certainly social organisation will be very weak. In an open country abounding with game the case is somewhat different, and there is reason to believe that in early days the Bushmen were divided into a number of large tribes, occupying tolerably well-defined tracts of country, each being under the jurisdiction of a paramount chief. The tribes were subdivided into groups under captains. They showed great attachment and loyalty to their chiefs, and exhibited a passionate love for their country. For hundreds of years these poor people have been harried and their hunting grounds taken away from them, and hence we must not judge the race by the miserable anarchic remnant that still persists in waste place. Nomad hunters do not progress far in civilisation by their own efforts, nor are they readily amenable to enforced processes of civilisation. Invariably they are pushed on one side or exterminated by peoples higher in the social scale.

When the written history of South Africa begins we find the Bushmen already being encroached upon by tbe Hottentots, who themselves sprang from a very early cross of Bantu with Bushmen. Culturally, as well as physically, they may be regarded as a blend of these two stocks. They combined the cattle-rearing habits of the Bantu with the aversion from tillage of the soil characteristic of the hunter; they became nomadic herders, who were stronger than the Bushmen, but who themselves could not withstand the Bantu when they came in contact with them, and they too were driven to less favourable lands and became enslaved by the invaders. All gradations of mixture took place until lusty uncontaminated Bantu folk forced their way into the most desirable districts. Still less could the Hottentots prevail against the colonists; their improvidence was increased by alcohol, and their indifference to the possession of land, due to their inherent love of wandering, completed their ruin.

The Bantu were cattle-rearers who practised agriculture. The former industry probably was transmitted from their Hamitic forefathers, who were herdsmen on the grassy uplands of north-eastern Africa, while the latter aptitude was probably due in part to their Negro ancestry. This duality of occupation led to variability in mode of life. In some places the land invited the population towards husbandry, in others the physical conditions were more suited to a pastoral life, and thus we find the settled Baronga on the one hand and the wandering Ovaherero on the other. The Bantu peoples easily adopt changes of custom; under the leadership of a warlike chief they become warlike and cruel, a common characteristic of pastoral peoples, while it is recorded that many of the Matabele, taken prisoners by the Barotse, settled down peacefully to agriculture. The history of the prolific Bantu peoples on the whole indicates that they were as loosely attached to the soil as were the Ancient Germans, and like the latter, at the slightest provocation, they would abandon their country and seek another home. This readiness to migrate is the direct effect of a pastoral life, and along with this legacy of unrest their Hamitic ancestors transmitted a social organisation which lent itself to discipline. These were the materials, so to speak, ready to hand when organisers should appear. Nor have such been lacking, for such names as Dingiswayo, Chaka, Dingan, Moselekatze, Lobengula, Moshesh, Sebituane, Cetewayo, and others are writ large in the annals of South Africa; and the statesman Khama is an example of what civilisation can do to direct this executive ability into proper channels.

Archaeology.

The archæology of South Africa is now attracting considerable local interest, and we may confidently expect that new discoveries will soon enable us to gain some insight into the dense obscurity of the past. It cannot be too strongly insisted upon that the methods of the archæologist should be primarily those of the geologist. Accurate mapping of deposits or localisation of finds is absolutely necessary. The workmanship of an implement is of little evidential value: the material of which it is made may be refractory, the skill of the maker may be imperfect, or he may be satisfied with producing an implement just sufficient for his immediate need; and there is always a chance that any implement may be simply a reject. The early generalisation of implements in England into two groups, Palæolithic and Neolithic, expressed a fact of prime importance, but now the classification has extended. It is obvious that the shapely palæoliths of the older gravels could not have been the first attempts at implement-making by our forefathers, and the presumed hiatus between the two epochs has been bridged over by evidence from sites on the European mainland. Our knowledge is increasing apace and an orderly sequence is emerging, but there are many interesting variations, and even apparent setbacks, in the evolution of industrial or artistic skill. In a word, sequence and technique must not be confounded, and our first business should be to establish the former on a firm basis; but, as I have just remarked, this can be accomplished only by adhering rigidly to the stratigraphical methods of the geologist. It would probably be to the interest of South African archæology if the terms "Eolithic," "Palæolithic," and "Neolithic" were dropped, at all events for the present, and it might prove advantageous if provisional terms were employed, which could later on be either ratified or abandoned, as the consensus of local archæological opinion should decide.

In certain lands of the Old World, north of the Equator, there was a progressive evolution from the Stone Ages, through a copper and a bronze age, to that of iron; but the stone-workers of South Africa appear to have been introduced to iron-smelting without having passed through the earlier metal phases, since the occurrence of copper implements is too limited to warrant the belief that it represents a definite phase of culture. The similarity of the processes employed in working iron by the different tribes of Africa, south of the equator, indicates that the culture was introduced from without, a conclusion which is supported by the universal use of the double bellows—a similar instrument is in use in India and in the East Indian Archipelago. Some ethnologists hold that Africa

owes to India its iron industry and other elements of culture, as well as the introduction of the ox, pig, and fowl. At all events, we shall probably not be far wrong if we assign a fair degree of antiquity to the knowledge of iron in tropical and southern Africa.

The characteristic metal of South Africa is gold, and its abundance has had a profound effect on the country, although, strange to say, it was not employed by any of the native races on their own initiative. We cannot tell when it was first discovered or by whom, but the hundreds of ruins scattered over a large extent of country, and the very extensive ancient workings, testify to the importance and the long continuance of this industry; for there can be no doubt that the builders of these wonderful remains came to this country mainly for the sake of its goldfields, though there must also have been an important trade in ivory, and incidentally in other local produce. Positive demonstration is as yet lacking concerning the nationality of the first gold-workers. This much is certain: they must have come to South Africa originally for some other product, since the aborigines did not work the metal, and it is most probable their quest was for ivory, and it was these hunters and traders who discovered the surface gold. Further, the discoverers must have come from a country where quarrying and metal-smelting were practised, and this implies the organisation of labour, for in early times, as history abundantly proves, mining was always undertaken by means of forced labour. The gold-workers, who probably came from Southern Arabia, belonged to a much higher social order than any of the peoples with whom they came in contact, and with their discipline in war and their industrial training they were able to subdue the Bantu inhabitants over immense tracts between the Zambesi and the Limpopo, to reduce them to slavery, to organise the working of the gold mines, and to establish a chain of forts and a system of communication with the coast. This occupation of the country by foreigners was purely for purposes of exploitation, and when, for reasons at present unknown to us, their hold weakened on the land, the whole enterprise fell to pieces, and the foreigners departed, they left indelible marks of their former presence on the face of the country, but in native industries and customs there is virtually no trace remaining of the rule of the more civilised Semitic overlord. The natives seem, as it were, to have awakened from a nightmare and straightway to have forgotten the hideous dream. Possibly this history may have been repeated more than once.

It is greatly to be deplored that in the past irresponsible prospectors have been permitted to rifle the ancient ruins for gold, with the result that not only have very numerous specimens of archæological interest been cast into the melting-pot, but at the same time collateral evidence has been destroyed, and thus valuable data lost to science. Even now the situation is not without its dangers, for the recently awakened interest in the ruins, and appreciation of their historical value, may lead to unconsidered zeal in excavation. After all, there is no especial hurry; what is perishable has long ago decayed, and so long as the ruins are sealed up by the rubbish that preserves them, no great harm can accrue, but in a few hours, by careless excavation, may be destroyed more archæological evidence than in centuries of neglect. Therefore it would be advisable for those in authority to consider carefully whether it is wise to lay bare new sites, unless proper examination and preservation can be ensured. The number of the ruins in Rhodesia is so great, and the area within which they occur so enormous, that it would be a very large undertaking for the Government systematically to investigate and permanently to conserve them all. Perhaps it would be possible to entrust some of this work to properly constituted local authorities, assisting them by grants and special facilities, but care would have to be taken to ensure the thorough carrying out of the work. Records of work done should be published, and the specimens preserved in authorised museums only. It is desirable also that every ruin should be scheduled under an Ancient Monuments Protection Act, and that an Inspector or Curator of Ancient Monuments should be appointed, who would be responsible for the excavation and preservation of all the monuments. To a less extent these remarks apply also to other parts of South Africa. All relics of the past, such, for example, as the pictographs in the rock-shelters of the Bushmen, should be jealously preserved and guarded from intentional or unwitting injury.

I trust my South African colleagues will forgive me if I have appeared too much in the character of a mentor. I have endeavoured to present a general view of the anthropological situation in South Africa, without burdening my remarks with details, and at the same time I have made bold to publish some of the conclusions which this survey has suggested; but there are other points on which I feel constrained to touch.

Recently Sir Richard Temple delivered an Address on "The Practical Value of Anthropology," in the course of which he said: "We often talk in Greater Britain of a 'good' magistrate or a 'sympathetic' judge, meaning thereby that these officials determine the matters before them with insight; that is, with a working anthropological knowledge of those with whom they have to deal. . . . It is, indeed, everything to him to acquire the habit of useful anthropological study before he commences, and to be able to avail himself practically and intelligently of the facts gleaned, and the inferences drawn therefrom, by those who have gone before him. . . . Take the universally delicate questions of revenue and taxation, and consider how very much the successful administration of either depends on a minute acquaintance with the means, habits, customs, manners, institutions, traditions, prejudices, and character of the population. In the making of laws too close a knowledge of the persons to be subjected to them cannot be possessed, and, however wise the laws so made may be, their object can be only too easily frustrated if the rules they authorise are not themselves framed with an equally great knowledge, and they in their turn can be made to be of no avail unless an intimate acquaintance with the population is brought to bear on their administration. For the administrator an extensive knowledge of those in his charge is an attainment, not only essential to his own success, but beneficial in the highest degree to the country he dwells in, provided it is used with discernment. And discernment is best acquired by the 'anthropological habit.' . . . . The habit of intelligently examining the peoples among whom his business is cast cannot be overrated by the merchant wishing continuously to widen it to profit; but the man who has been obliged to acquire this kind of knowledge without any previous training in observation is heavily handicapped in comparison with him who has acquired the habit of right observation, and, what is of much more importance, has been put in the way of rightly interpreting his observations in his youth."

In referring to civil-servants, missionaries, merchants, or soldiers, Sir Richard Temple went on to say: "Sympathy is one of the chief factors in successful dealings of any kind with human beings, and sympathy can only come with knowledge. And not only does sympathy come of knowledge, but it is knowledge that begets sympathy. In a long experience of alien races, and of those who have had to govern and deal with them, all whom I have known to dislike the aliens about them, or to be unsympathetic, have been those that have been ignorant of them; and I have never yet come across a man who really knew an alien race that had not, unless actuated by race-jealousy, a strong bond of sympathy with them. Familiarity breeds contempt, but it is knowledge that breeds respect, and it is all the same whether the race be black, white, yellow, or red, or whether it be cultured or ignorant, civilised or semi-civilised, or downright savage."

I have quoted at length from Sir Richard Temple, as the words of an administrator of his success and experience must carry far greater weight than anything I could say. I can, however, add my personal testimony to the truth of these remarks, as I have seen Britons administering native races on these lines in British New Guinea and in Sarawak, and I doubt not that I shall now have the opportunity of a similar experience in South Africa.

In this connection I ought to refer to what has been already done in South Africa by the Government. In the year 1880 the Government of Cape Colony, confronted by

the problem of dealing with the natives, appointed a Commission to inquire into the native laws and customs which obtained in the territories annexed to the Colony, especially those relating to marriage and land-tenure, and to suggest legislation, as well as to report on the advisability of introducing some system of local self-government in the native territories annexed to the Colony. The example was shortly afterwards followed by the Government of Natal, which had native problems of its own. These two Commissions collected and published a considerable amount of evidence, valuable not only for the immediate purpose in view, but also for the purposes of science. Before the late war came to a close the Anthropological Institute of Great Britain and Ireland and the Folklore Society addressed to Mr. Chamberlain, then Colonial Secretary, a memorial praying that on the conclusion of peace a similar Commission should be issued to inquire into the customs and institutions of the native tribes in the Transvaal and the Orange River Colony, and, with a view to the accomplishment of more directly scientific ends, praying that at least one anthropologist of eminence unconnected with South Africa should be included in the Commission. The prayer of the memorialists was bluntly refused. When, however, in the course of reorganisation of the administration, a conference was held at Bloemfontein in 1902 of the Ministers of the various colonies, protectorates, and territories, to discuss native affairs, they found themselves, in the words of Sir Godfrey Lagden, "much confused because the laws and the conditions of all the colonies were different." This was exactly what the memorialists had told Mr. Chamberlain. So the conference determined on the appointment of a Commission of Inquiry, which was issued in due course by Lord Milner in September, 1903, and reported on January 30 last. The evidence taken by this Commission, as well as that taken by the previous Commissions, is of a very valuable character. But, like those Commissions, its object was exclusively administrative. Consequently the evidence is only incidentally of ethnological interest, and it by no means covers the whole ground. The social life and marriage laws are to a great extent laid before the reader, but there is no attempt to distinguish accurately between one tribe and another; the native institutions are discussed only so far as they have a practical bearing on administrative questions. There is no attempt to penetrate to the underlying ideas and beliefs, and the vast domain of religion lies for the most part outside the ken of the Commissioners. Admirable, therefore, as is the work done by these Commissions, it is but a small part of what must be undertaken if an accurate account of the natives of South Africa is to be obtained and preserved for scientific use, and as an historical record. What is wanted is that the Government should undertake this enterprise in the same way as the Governments of the United States, Germany, the Netherlands, and other countries investigate their native races, or, failing this obvious duty of a Government, that adequate assistance should be given to societies or individuals who may be prepared to take the matter in hand.

Unfortunately it is not unnecessary to insist on the need there is for us to consider seriously what at any particular time is most worth investigating, and not to let ourselves drift into any casual piece of work. Let us apply that simple test to South Africa, and ask ourselves, What most needs doing in anthropological research in South Africa?

So long as actual wanton destruction is not taking place, local archæological investigation can wait. I do not mean to suggest that those who have the opportunity should not devote themselves to this important subject; many can do good work in archæology who have neither opportunity nor inclination for other branches of anthropology, and the British South Africa Company has shown and probably will continue to show a real interest in this work. But our first and immediate duty is to save for science the data that are vanishing; this should be the watchword of the present day.

Observations in South African anthropography are lamentably deficient. Although scattered up and down in books of travel and in missionary records there are descriptions of individuals, and in some cases a few salient features of a tribe are noted, yet we have few precise descriptions of communities that are of value for comparative purposes. Anthropometrical data are everywhere wanting; very few natives have been measured, and the measurements that have been made are insufficient both as regards those actually taken and the number of individuals measured. The interesting subject of comparative physiology is unworked. We have no observations in experimental psychology, and very few trustworthy data in observational psychology. Here, then, is a large field of inquiry.

I am not competent to speak concerning linguistics, but from what I have read I gather that a very great deal yet remains to be done, at all events in phonetics, grammar, and comparative philology.

In general ethnology a considerable amount of scattered work has been done, but no one tribe has been investigated with scientific thoroughness; the best piece of work hitherto accomplished in this direction is the admirable memoir on the Baronga by the missionary H. A. Junod, which leaves little to be desired. It would be well worth while for students to make exhaustive studies of limited groups of people, tracing all the ramifications of their genealogies in the comprehensive method adopted by Dr. Rivers for the Torres Straits Islanders and for the Todas; this method is indispensable if it is desired to obtain a true conception of the social structure of a people, their social and religious duties, the kinship relationships, and other information of statistical and sociological value. Other fruitful lines of inquiry are the significance of the form and ornamentation of objects and the symbolism (if there is any) of the decorative art, a subject which, as far as I am aware, is absolutely untouched. Even the toys and games are worth investigation. Hardest but most important of all, there is that intricate complexus of action and belief which is comprised under the term "religion." This needs the most delicate and sympathetic treatment, although too often it has been ruthlessly examined by those who were more prone to seek the ape and the tiger and vain imaginings in the so-called "superstitious" practices of these poor folk. They are laggards along the road which our more favoured ancestors have trod, but they all have their faces set in the same direction as our own, towards that goal to which we ourselves are striving. To induce natives to unbosom themselves of all that they hold secret and sacred and to confess their ideals and inspirations requires more than an ordinary endowment of patience, tact, and brotherly kindness; without these qualities very little can be gathered, and the finer side of native thought and feeling will for ever remain a sealed book to the European. In referring to this subject it should not be overlooked that the best account we have of the religion of the Zulu-Xosa peoples is due to the labours of Bishop Callaway. The number of native texts, including folk-tales, published by him are especially valuable, as they throw light from all sides upon the native mind, and it is greatly to be regretted that he lacked the pecuniary and other encouragement that was necessary for the completion of his labours. The most urgent of all the foregoing lines of inquiry are the most elusive; these are the ideas, beliefs, and institutions of the people, which are far less stable than are their physical characteristics.

These are some of the lines of research that await the investigator. The field is large, but the opportunities are fleeting. The Kattea, Bushmen, and Hottentots are doomed, and new social conditions are modifying the Bantu peoples. Here again we must apply the test question, Which of these peoples most needs investigation? The answer again is obvious. Those that will disappear first. All over South Africa this work is pressing. For some tribes it is too late. It would be a memorable result of the meeting of the British Association in South Africa if it should lead to an exhaustive study of those most interesting people, the Kattea, the Bushmen, and the Hottentots. They represent very primitive varieties of mankind, but their numbers are rapidly diminishing, and, as races, they have no chance of perpetuity. What judgment will posterity pass upon us if, while we have the opportunity, we do not do our best to save the memory of these primitive folk from oblivion?

Report and Proceedings of the South African Intercolonial Commission on Native Affairs, 1903-05. Cape Town, 1905. (Report, 1 vol. Minutes of Evidence, 5 vols.)

The foregoing list of books is manifestly very incomplete. A considerable amount of information concerning the natives will be found in numerous books by missionaries, travellers, and sportsmen.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. E. G. BAWDEN has entrusted Mr. Edgar Speyer "with a sum in cash and securities of about 100,000*l.* to be applied to purposes of charity and benevolence, and for the advancement of knowledge, especially in aid of human suffering." After careful consideration, this sum has been apportioned for various good purposes in the form of capital to be vested in trustees, and to be known in each case as the "Bawden Fund." The largest allotment is in aid of advanced university education and research, and for this purpose a gift of 16,000*l.* is made to complete the sum of 200,000*l.* required to bring about the incorporation of University College in the University of London.

THOUGH the corporation of the Massachusetts Institute of Technology has taken action in connection with the proposed alliance of the Institute with Harvard University, the faculty and alumni have expressed their disapproval of the scheme. Before the proposed agreement can be consummated there will be necessary at least three decisions by the Supreme Judicial Court upon the grave legal questions involved, action by the Harvard authorities, and possibly further consideration by the corporation of the institute and an appeal for legislative sanction. A league has therefore been organised "to oppose the plan of alliance under consideration, or any other plan which may impair the self-government of the institute, and to secure for the past students a proper share in its administration."

PROF. W. HALLOCK, professor of physics in Columbia University, New York City, writes to say that the proposal of the Emperor of Germany for the temporary interchange of professors with America, referred to in NATURE of July 20 (p. 285), had nothing to do with the courses arranged at that university, as they were planned three years ago, when Prof. Hallock took charge of the department of physics. The lecturers are not exchanged; they are appointed as "non-resident lecturers" for the year, and receive an honorarium for their courses. The visiting lecturers at Columbia University for the year 1906-7 are Prof. Lummer, of Breslau, and Dr. J. Larmor, F.R.S.

A COPY of the prospectus of the Redruth School of Mines for 1905-6 has been received. Situated in the centre of the Cornish mining district, the school is devoted wholly to instruction in mining and allied subjects essential to the training of mining engineers, assayers, and mine-surveyors. Practical work in mining is carried on at the

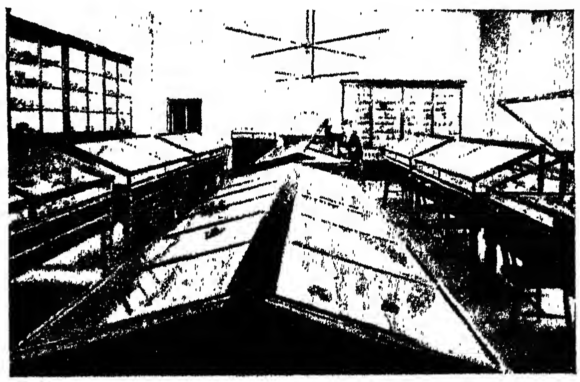

FIG. 1.—The Hunt Museum, Redruth School of Mines.

Basset mines and at other mines in the vicinity under the supervision of the school instructor. Success in examinations in particular subjects held at the school by the Board of Education, the City and Guilds of London Institute, and the County Council of Cornwall forms part of the requirements for a school certificate. One wing of the school building is occupied by a large mineral gallery erected in memory of the late Mr. Robert Hunt, F.R.S., keeper of the mining records. This museum, which contains a very valuable collection, offers great facilities for mineralogical study.

CORRESPONDENCE between the Bengal Government, the Government of India, and the Secretary of State for India upon the subject of the establishment of a school of mines in India, extending over the period from May 21, 1904, to August 3, 1905, has been published. On the advice of a strong committee, the proposal adopted is to provide a curriculum of mining instruction at the Sibpur Engineering College, Calcutta, with practical instruction in the mining districts. A professor of mining engineering is to be appointed in England at a salary of 750 rupees to 1000 rupees a month. The scheme also contemplates the temporary appointment for five years of a peripatetic mining instructor and a native assistant, who will be called upon to give free instruction in the mining districts. The whole scheme involves an initial expenditure of 8500 rupees on the equipment of Sibpur College, and an annual recurring expenditure of 16,000 rupees in connection with that college, and of 15,000 rupees for peripatetic instruction in the mining districts. For a scheme so promising in economic benefit to India, the outlay appears extremely moderate.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 8.—"The Elastic Properties of Steel at High Temperatures." By Prof. B. **Hopkinson** and F. **Rogers**. Communicated by Prof. Ewing, F.R.S.

In the experiments described in this paper, the elastic properties of steel and iron have been investigated at higher temperatures, ranging up to 800° C., and for stresses greatly below that required to rupture the material. The authors have found that as the temperature rises the stress-strain relations undergo a remarkable change, which may best be expressed by saying that what is variously called the "time-effect," or "elastische nachwirkung," or "creeping," increases greatly with the temperature. Steel, at high temperatures, behaves like indiarubber or glass; if it is stressed for a time, and the stress removed, it does not at once recover, but after the immediate elastic recovery there is a slow contraction perceptible for many minutes. Such "creeping" can be detected at the ordinary temperature, but at a red heat it attains a different order of magnitude, becoming (in its total amount) a substantial fraction of the whole deformation.

This phenomenon is analogous to residual charge in glass and other dielectrics; the stress corresponding to the electric force, and the strain to the electric displacement. Whether the law of linear superposition of the effects of stresses—closely followed in the electrical analogy—is true for hot steel or iron, is an interesting question which the apparatus used was hardly sufficiently delicate to answer.

The magnitude of this effect in steel may best be gauged by comparing it with other cases of the same kind, *e.g.* with the slow recovery of a glass fibre after twisting; if such a fibre be twisted through a considerable angle for several hours, it will recover all but one-fiftieth of the twist within two or three seconds of the removal of the stress. The remaining slow "creep," amounting to one-fiftieth of the whole deformation, corresponds to the slow return of the steel. In indiarubber, in certain circumstances, 10 per cent. of the strain disappears in time after the removal of the stress. But in steel, at 600° C., the proportion is about 15 per cent.

Another effect of "creeping," such as the authors have observed, is to make the determination of Young's modulus a matter of some uncertainty. Thus the extension of the bar at 600° C. produced by a given load varies 15 per cent. or more, according to the time of application of the load. When, however, the load is applied for a very short time, say of the order of one or two seconds, the strain produced seems to approach to a definite limiting value which is the instantaneous extension or contraction of the bar observed in the experiments when the load is applied or removed. It seems reasonable to define Young's modulus for a metal in this state, as the stress divided by this limiting instantaneous strain. It is then independent of the manner of loading, and is a definite physical constant; otherwise not.

"On the Refractive Index of Gaseous Fluorine." By C. **Cuthbertson** and E. B. R. **Prideaux**. Communicated by Sir William Ramsay, K.C.B., F.R.S.

The authors have determined the refractive index of gaseous fluorine for sodium light by means of Jamin's refractometer. Five experiments gave values for the refractivity $(\mu-1)$ 10^6 of 195, 177, 192, 194, and $198\frac{1}{2}$. The discrepancy exhibited by the second experiment can be accounted for, and it is believed that the mean of the other four experiments, 195, is within 2 or 3 per cent. of the true value.

In a recent paper (*Phil. Trans.*, A, vol. cciv. p. 323), one of the authors has attempted to show that the refractivities of the different members of the same chemical group are related in the ratios of small integers; and it was observed that, if this coincidence were not due to chance, the refractivity of fluorine should bear to that of chlorine the ratio of 1 to 4, which those of neon, oxygen, and nitrogen bear to argon, sulphur, and phosphorus respectively. This prediction has been verified. The refractivity of chlorine for sodium light is 768, or 192×4; and that now found for fluorine is 195, a discrepancy of $1\frac{1}{2}$ per cent., which is well within the limits of error of the experiment.

Paris.

Academy of Sciences, August 28.—M. Troost in the chair.—The ultra-violet spectra of the reversing layer during the total eclipse of May 28, 1900: H. **Deslandres**. An account of the apparatus employed, and a short list of the principal lines of titanium, vanadium, and chromium observed.—On a differential equation of the fourth order: Gaston **Darboux**.—On transcendental numbers: Ed. **Maillet**.—Researches on irradiation: Adrien **Guébhard**.—On a method suitable for the study of a luminous phenomenon varying in intensity with the time. Application to the determination of the instantaneous velocity of a rotating mirror and to the study of the Hertzian spark: A. **Turpain**. The arrangement is a modification of the Foucault experiment for the determination of the velocity of light. The receiving eye-piece is replaced by a photographic plate, and the spark is placed between the rotating and fixed mirrors. The measurement of the distance on the negative between the two images, the one caused by the light travelling directly and the other by reflection from the fixed mirror, and of the distances apart of the portions of the apparatus, gives an accurate determination of the velocity of the mirror, the velocity of light being taken as known. The method has been also applied to the study of the spark given by a Hertzian excitor and resonator, but the description of this part of the work is reserved for a later communication.—A new group of protophytic parasites, Ecrinides: L. **Léger** and O. **Duboscq**.—A contribution to the cytological study of the Cyanophyceæ: A. **Guilliermond**.—*Sterigmatocystis nigra* and oxalic acid: P. G. **Charpentier**. This mould, when cultivated in Raulin's fluid, never secretes oxalic acid before spore formation takes place, but sporulation acts only indirectly in causing the secretion, this being caused by the exhaustion of the medium.

THURSDAY, SEPTEMBER 14, 1905.

ASTRONOMY FOR TRAVELLERS.

Handbuch der geographischen Ortbestimmung für Geographen und Forschungsreisende. By Dr. Adolf Marcuse. Pp. x+342+2 charts; illustrated. (Brunswick: Friedrich Vieweg und Sohn, 1905.)

A SHORT preface by the author tells us that this book is designed, in the first place, to give assistance to geographers and explorers, to aid students of the mathematical sciences and pupils in the higher schools, and to serve as an introduction to those parts of astronomy which, since they are concerned with the determination of time and of position on the earth's surface, have an important influence on everyday life. One does not expect, therefore, a description or an explanation of the nicest details that lead to the greatest accuracy, but rather the exhibition of the general principles on which the determination of coordinates depends; and on the whole this ground is fairly well covered, both from a theoretical and practical point of view. But when an author poses as a teacher, we are apt to examine his book a little closely, to see if he has shown any sign of clearly apprehending the difficulties that learners and pupils encounter when attacking a new subject, and made any adequate effort to remove these difficulties. There is no evidence of any particular care in this direction, though, of course, it is no easy matter to detect beforehand where the pitfalls and misconceptions on the part of the pupil will arise, and points that seem to one teacher to demand a lengthened explanation or further illustration do not present themselves in the same way to the judgment of another expert.

But there is another test which may be more safely applied. Are any matters introduced which give needless complexity, or delay the continuous progress of the work? In this respect we think the author is not altogether blameless. For instance, the section on "probable error" and the solution of equations by the method of least squares seems on this ground out of place. The subject in the space given to it is not, and cannot be, treated exhaustively; it must leave but a very hazy notion in the student's mind, and the application of the theory is not wanted in the discussion of the rough results which are derived from the instruments that are employed. Similarly, what has a traveller dealing with approximate values of latitude and longitude to do with the small variations arising from the motion of the Pole? It seems a little inconsistent to suggest a degree of accuracy in the final results which cannot be realised with the particular means adopted.

If these are details into which it would have been better not to have entered, there are, on the other hand, omissions, or at least what appear to be omissions, to which some reference should have been made. Thus, by way of illustration, we may mention the absence of all reference to the sextant and artificial horizon in the portion of the book devoted to the description of instruments. The author is perhaps desirous that his book should not be confounded with the many treatises on nautical astronomy and the methods of reduction therein employed; but the sextant has as distinct a value in exploring new country as the chronometer, to which the author devotes a very satisfactory section. In the determination of longitude, the sextant applied to the measurement of lunar distances affords more trustworthy results than does the observation of Jupiter's satellites, on which the author would apparently rely. Occultations of stars by the moon, which is merely a particular case of the method of lunar distances, are referred to at considerable length. A numerical example of the application of the method is worked out in full, and in all the various methods of deriving the latitude and longitude detailed examples are furnished. This is a very satisfactory feature of the book, and we could have wished that the selection of examples had been more varied and had included the method of lunar distances.

If these omissions seem to us to be slight blemishes on an otherwise excellent book, it is with the greater pleasure that one can turn to the consideration of the sections which treat of matters of more novelty and originality. In the chapter devoted to instruments we meet with a "level-quadrant" (Libellenquadrant) with which we are unfamiliar, and though it appears to be distinctly inferior to the sextant, it may be of advantage in some situations. The peculiar feature of the instrument consists in the fact that the bubble of a level carried on a rotating arm is reflected into the field of view and made to do the same service as the reflection of the sun to the horizon by means of the ordinary arrangements found in the sextant. In the case of determining the position of a balloon when the earth may be invisible owing to clouds passing beneath the observer, such an arrangement can be used with effect. In the chapter on the determination of a balloon's course, the method is applied with very considerable success. The path of a balloon from Berlin to a point beyond Breslau, a complete run of about 400 kilometres, is worked out, and the average error appears to be about 16 kilometres. This would be a large error on board ship, but the conditions are not the same, nor is there the same necessity for accuracy. The aëronaut has simply to take care that he does not run out to sea; the navigating officer has to make a land fall. The calculations in this section have been materially shortened by the use of the so-called Mercator function, which, in the examples given, does away with the necessity of logarithmic tables, and suggests a method of working that seems to be well worth the little study that is necessary to master the application of it.

Lastly, we may mention an ingenious method of determining approximately geographical positions without the use of graduated instruments. Threads supporting a weight at the apex of a triangle so as to ensure verticality and to give steadiness can be hung on tent poles, and over these threads the transit of stars can be observed with the naked eye. Then, knowing the time, the latitude, longitude, and azimuth can be approximately derived; and when

instruments have been injured or delayed, or are generally inaccessible, such methods are not to be despised. It would be an admirable exercise for anyone, whether he travels or not, to accustom himself to the use of such tools, and learn to what degree of accuracy he can rely on such devices.

THE EVOLUTION OF HUMAN SOCIETY.

La Sociologie génétique. By François Cosentini. Introduction by Maxime Kovalewsky. Pp. xviii +205. (Paris: F. Alcan, 1905.) Price 3.75 francs.

IN a short compass this book gives an excellent bird's-eye view of a very wide territory. It begins with a discussion of the data available for the study of the evolution of human society. Even animal associations are not neglected, but, naturally, more space is devoted to the beliefs and customs of savage tribes. Our author decides wisely with regard to primitive man that much is to be learnt thus. But he deprecates rash inferences. The ancestors of civilised man, there is reason to believe, never ceased to make progress. The savages of the present day have stagnated, and may, in some cases, have retrograded. Still, when the theories that suggest themselves to the investigator of savages and their ways are modified and corrected by the study of the institutions, the beliefs, the folk-lore of civilised peoples, it is probable that the risk of serious error is reduced to very small proportions.

M. Cosentini decides in favour of a polyphyletic origin of the human race, arguing partly from the reduced fertility observable when two widely different types interbreed. After a brief but interesting account of the Palæolithic and Neolithic ages, he deals with the origin of the family. Here, as elsewhere, he shows sound judgment in his treatment of the various rival theories. He refuses to regard the patriarchal family as primitive. The more primitive the community the less sign is there of patriarchal authority. On the other hand, it would be foolish to maintain that there was ever a time in which woman was absolutely predominant. This view is precluded by the fact that primitive man had to wage incessant war against wild beasts and almost incessant war against hostile tribes. But there is abundant evidence that there was a time when a man was known as his mother's son and not as his father's, when pedigrees were traced through the female line, and when women had much more power and influence than at a later period when the patriarchal system had been developed. When the tendency changed and the paterfamilias became an autocrat within his own household, civilisation made great progress.

The family has been the nucleus which has made the higher civilisation possible, a point which, perhaps, M. Cosentini does not sufficiently recognise. Our author is, no doubt, right in holding that the idea of the family grew out of the idea of private property. The wife was the property of her husband. In very many cases he had captured her as he had captured his cattle. But with regard to monogamy, M. Cosentini does not bring out the interesting fact that in northern climes, where it is most firmly rooted, it derives its strength mainly from the fact that one man's labour suffices for the feeding and clothing of only a small number of children. Even among animals we find the same thing. Where the work of both parents is required for the bringing up of the young, there the system of pairing is the rule. Where the young are precocious and are soon able to fend for themselves, polygamy arises.

On the remainder of the book want of space forbids us to comment at length. It deals with animism, myths, language, religion, morality, law, the origin of social classes, art, industry, and commerce. The style is clear; and throughout the book M. Cosentini proves himself a fair critic and a clear-headed thinker.

F. W. H.

OUR BOOK SHELF.

Trees. By H. Marshall Ward. Vol. iii. Flowers and Inflorescences. Pp. xii+402. (Cambridge: The University Press, 1905.) Price 4*s.* 6*d.* net.

THE first two volumes of the above work have been previously noticed in these columns. The present volume, which deals with flowers, is, like the others, divided into two parts. Part i. deals with the flower in general. The author has been very successful in his treatment of this vast subject; he has brought together and arranged his facts in such a clear and simple manner that the beginner should have no difficulty in gaining a very comprehensive knowledge concerning the different kinds of inflorescences, the structure and development of flowers, as well as the meaning of their various forms and modifications. So far as possible technical terms have been carefully avoided, but at the same time it is quite impossible to treat a subject like this without using one or two terms which have a special meaning of their own which cannot be readily put into every-day language. Wherever such expressions are used their meaning is always carefully explained, and at the end of the book a useful glossary is given which will remove all mystery concerning these terms should any such exist.

The author has naturally confined himself to a critical examination of the flowers of trees and shrubs, and the student will find here an epitome of the natural system of classification, and when this epitome has been mastered he will be in a position to understand the structure and form of the flowers of cultivated and wild herbaceous plants as well.

Part ii. is more of the nature of a flora, *i.e.* the author has given in tabular form a general conspectus of woody plants and their flowers, by which means any given species may be easily diagnosed at flowering time.

It is a well known fact that the willows are almost, if not, the most difficult family to deal with as regards their identification. Apart from their tendency to hybridise with each other, the willows are diœcious, which renders their identification very difficult when only one kind of flower is available. The author has very ingeniously overcome this difficulty by giving a special table as an appendix wherein the separate characters of the male and female flowers are used for the purposes of diagnosis.

This volume, like the other two, is profusely illustrated. There is also a very useful and exhaustive index at the end of the book. While vol. i., "Buds and Twigs," is a book for the winter study of trees and shrubs, we have in vol. iii. a book which is specially adapted for use in summer.

A Laboratory Guide in Elementary Bacteriology. By Dr. William Dodge Frost. Third revised edition. Pp. xiii+395. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 7*s.* net.

THIS book is, as stated in the title, a guide for practical laboratory work in elementary bacteriology. The student is taken step by step through the various processes of cleaning and setting up apparatus, sterilisation, preparation of culture media, demonstration of gas production, and detection of certain chemical products, the result of microbial activity. The isolation and cultivation of bacteria, and staining methods, are then considered, and a few exercises are given on the physiological properties of micro-organisms, such, for example, as the influence of the reaction of the medium on growth, the effects of desiccation, &c. The student is next introduced to the systematic study of types, first of non-pathogenic and then of the chief pathogenic forms. In this, as well as in the preceding portions of the book, a heading only is given, and to the exercises and practical work, and pages are left blank for the student's own notes, subheadings indicating what he should observe and look for, the facts observed being entered up by the student himself. In addition, outline diagrams are given of culture tubes which are to be filled in with the students' own drawings. In this way the guide becomes a permanent note-book and record of the student's work. Finally, directions are given for the inoculation and *post-mortem* examination of animals, and a key index of the characters of the more important species concludes the volume. At the end of each section a reference is given to the principal manuals and text-books of bacteriology, such as Abbott's, Chester's, Eyre's, Hewlett's, Muir and Ritchie's, Sternberg's, &c., so that the student may read up the subject. So far as we have been able to observe, the directions given are clear and concise, the exercises judiciously chosen, and the book is singularly free from errors. That a third edition should have been called for is sufficient evidence of the need for such a book, and for those who desire and work from a laboratory guide, and to lighten the labour of full and complete note taking, it may be strongly recommended. R. T. HEWLETT.

Nature-study Lessons for Primary Grades. By L. B. McMurry. Pp. xi+191. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1905.) Price 2*s.* 6*d.* net.

DR. C. A. MCMURRY, who has written the introduction to this volume, is one of the chief recognised authorities in America on elementary scientific education, and, indeed, on elementary education in general, and since he has probably read the proofs and given a general approval to the text, the work may be regarded as being written by one having authority. The plan of the work is to take a series of animals and plants and to show how the lessons to be learnt from them may be taught to pupils of tender years, or rather how the pupils may be trained to find out the meaning of the lessons for themselves. Having gained the confidence and attracted the interest of the pupils, the first object of the teacher should be to endeavour to foster and develop their own powers of observation and of drawing simple conclusions from such observations; and for this purpose the method adopted in the volume seems admirably adapted. Although it is not expected that all teachers will select the same objects for their texts, or that they should all follow by any means the same method of instructing, there can be no doubt of the advantage of having a list of those objects which appear most suitable for the purpose, and also of the benefits which younger teachers may derive from a perusal of the manner in which a more experienced member of their body handles her subject.

While the book appears admirably adapted for its purpose so far as teaching in America is concerned, it seems to require a word of warning when put into the hands of British teachers, and we think it would have been well had a special note to this effect been inserted in the copies intended for sale in this country. For instance, the teaching suggested in the chapter headed "The Robin" will apply for the most part excellently well to the bird so designated in this country; but when the inexperienced teacher (who is unaware that the so-called American robin is not our own familiar red-breast) reads that robins lay blue eggs he, or she, will be apt to put the book aside with the remark that the author does not know her subject. Again, it would much have simplified matters had the English teacher been informed that the plants known in America as "Morning-Glory" include the one commonly called *Convolvulus major* in this country.

With these limitations (which refer only to its issue in this country), we have nothing but praise to bestow upon Dr. and Mrs. McMurry's efforts to establish elementary biological teaching upon a sensible and practical basis. R. L.

Einführung in die Vektoranalysis mit Anwendungen auf die mathematische Physik. By Dr. Richard Gans. Pp. ix+226. (Leipzig: Teubner, 1905.) Price 8 marks.

THIS well-written book gives the usual definitions of scalar and vector products, introduces the now familiar differential operators "div" and "rot" (or "curl"), and uses them skilfully in the simpler applications of the line, surface, and volume integrals, associated with the names of Green, Gauss, and Stokes. The necessity for vector analysis in electromagnetic work is becoming more generally recognised, and Dr. Gans deserves the thanks of all for his able presentation of the outlines of the method, which, nevertheless, is at its best a "Quaternionenstenographie," as C. Neumann felicitously nicknames it. One has only to compare the demonstrations here given, which are primarily Cartesian and are then transformed into the concise vector notation, with corresponding quaternion demonstrations, such as may be found in Joly's "Manual," to see plainly the analytical gulf which separates Hamilton's *calculus* from other vector analyses, which are essentially shorthand *notations*. The mathematical historian of the future will find much food for thought in the mental shortsightedness of many vector analysts who delight in the use of contraction symbols like *grad, rot, div,* but despise the Hamiltonian selective symbols V and S, which with the real ∇ give the whole theory in exquisite compactness and flexibility. On a folding sheet at the end Dr. Gans gives a table of eighteen transformation formulæ, which presumably must all be learned off by rote. There does not seem to be any resemblance among the formulæ (h), (o), (q), which give respectively the equivalents of $[\mathbf{A}[\mathbf{BC}]]$, rot rot $\mathbf{A}$, rot $[\mathbf{AB}]$. In the quaternion notation $V\mathbf{A}V\mathbf{BC}$, $V\nabla V\nabla\mathbf{A}$, $V\nabla V\mathbf{AB}$, they are seen to be of the same "form," and are, indeed, analytically amenable to the same treatment. This is but one illustration of the inferiority of the "Quaternionenstenographie" to the real quaternion analysis. Dr. Gans gives interesting applications in hydrodynamics and in Maxwell's electromagnetic theory, but is limited somewhat by the fact that in this introduction there is no account taken of the linear vector function or matrix.

Observations of the Total Solar Eclipse in Tripoli, Barbary.

OUR eclipse took place in the midst of the fierce heat of the *Gibleh*, or Sahara sirocco; but an hour or two before totality the wind very fortunately changed, and brought skies of the highest possible optical transparency. There was no wind, and the conditions, except for the intense heat, which we momentarily feared would snap our great cameras, were the most nearly perfect imaginable at a sea-level station.

Unfortunately, on account of leaving home at very short notice, we brought no spectroscopic outfit, and our efforts were directed solely toward coronal photography with automatic and semi-automatic coronagraphs, and to exposure of plates for the slightly suspected intra-Mercurial planet. Other branches of our work related to coronal sketches, both with and without occulting discs, and to shadow band observations, both optically and photographically.

By the kindness of His Majesty's Government, represented by Mr. Alfred Dickson, Vice-Consul, the American expedition from Amherst College was permitted to establish its instruments on the terrace of the consulate, in the midst of the white city—in precisely the same spot occupied for the similar eclipse of 1900.

Many citizens of Tripoli took immediate and constant interest in our operations, and contributed very greatly to our success by their liberality in granting that service which only the chief of an expedition remote from home can fully appreciate. I am glad to mention especially Mr. W. F. Riley, Mr. W. H. Venables, Maris de Nunes Vais, the excellent photographer of the expedition, and Etim Bey, a Turkish gentleman resident in Tripoli, whose unique collection of photographic and mechanical appliances was frequently and helpfully drawn upon.

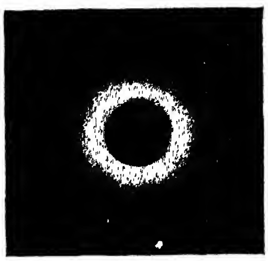

FIG. 1.—Total Solar Eclipse of August 30. Photographed at Tripoli.

The observations of shadow bands were conducted by parties organised by Mrs. Todd and Miss Todd, and will be reported to my friend Mr. Lawrence Rotch, of Blue Hill, at whose request they were made. These bands were seen as early as ten minutes before totality, and had many remarkable and pronounced peculiarities. They were wavering and narrow, moving swifter than one could walk, at right angles to the wind, their length with it, and waxing and waning five times during the eight minutes preceding totality.

The coronal sketches revealed nothing out of the ordinary. Extended rays beyond the occulting discs were looked for eagerly, but the disc (8 inches diameter at 35 feet distance) covered everything. The sky and general illumination were exceptionally bright. Totality as predicted was 3m. 9s. in duration; as observed 3m. 6s.

Our chief and largest instrument was a photographically corrected lens by Clacey, of 12 inches full aperture. To this was attached an orthochromatic screen for photographing Baily's beads, and a Burckhalter occulter as described by the writer four years ago in the *Monthly Notices*. Of the results obtained with this instrument I shall write elsewhere; about twenty exposures were made with it, and the beads are excellently shown in the accompanying photograph. The occulter was only in part successful.

Alongside it were the large Clark cameras, containing a pair of 3-inch lenses of 11 feet 4 inches focus, which took plates on which are a great number of stars, not yet fully examined. Owing to the unexpected brilliancy of the sky, the plates were exposed longer than would seem to have been wise. Everything to the eighth magnitude seems to have been caught, however.

A third instrument was a $3\frac{1}{2}$-inch Goerz doublet of about 18 inches focus, from which I removed the back lens, increasing the focal length to $33\frac{1}{2}$ inches. This was attached to one of the automatic movements used in my previous expeditions of 1896, 1900, and 1901. It was geared up to a rate of 265 photographs during the 189 seconds of totality, the exposure being about $\frac{1}{4}$ second for each. Most of these pictures are very good, and I enclose a print from one of them (Fig. 1), which does not, however, do the original negative justice. The corona was much less impressive, it strikes me, than other coronas I have seen—1878 and 1900 in clear skies, and 1887, 1889 (*b*), 1896, and 1901 in clouds; in fact, the shadow bands and Baily's beads seem to have been rather more interesting to the general observer than the corona itself.

On the Class of Cubic Surfaces.

IN Salmon's "Geometry of Three Dimensions," the classes of the twenty-three different species of cubic surfaces are stated; but the process by which these results are obtained is not obvious. I therefore propose to indicate an easy method.

The class of a plane curve is equal to the number of tangents which can be drawn from a point not on the curve; hence the class of a curve is equal to the degree of its reciprocal polar. And since the line joining two points on a surface corresponds to the line of intersection of two tangent planes to the reciprocal surface, it is necessary, in order to make the theories of curves and surfaces correspond, to define the class m of a surface to be equal to the number of tangent planes which can be drawn through a given straight line. Let $(\alpha, \beta, \gamma, \delta)$ be quadriplanar coordinates referred to a tetrahedron of reference ABCD; then the equation of the tangent plane at any point (f, g, h, k) is

$$\alpha\frac{dF}{df} + \beta\frac{dF}{dg} + \gamma\frac{dF}{dh} + \delta\frac{dF}{dk} = 0 \qquad (1)$$

and if this plane passes through the line CD, we must have $dF/dh=0$, $dF/dk=0$. Hence the points of contact of the tangent planes which pass through CD are the points of intersection of the three surfaces

$$F=0,\ dF/d\gamma=0,\ dF/d\delta=0 \qquad (2)$$

and their number is equal to $n(n-1)^2$, which is the value of m for an anautotomic surface. The elimination of (α, β) between (2) will furnish a binary quantic in (γ, δ) the degree of which is equal to the class of the surface.

It is obvious from geometrical considerations that a conic node must diminish the class by 2. The equation of a cubic having a binode B_3 is $\alpha\gamma\delta+u_3=0$, where u_3 is a ternary cubic in (β, γ, δ). Differentiating with respect to γ and δ, and then putting $\delta=\lambda\gamma$, we obtain

$$\left.\begin{array}{r} \lambda\alpha\gamma^2+u'_3=0 \\ \lambda\alpha\gamma+du'_3/d\gamma=0 \\ \alpha\gamma+du'_3/d\delta=0 \end{array}\right\} \qquad (3)$$

where the accents denote what the quantities become when δ is put equal to $\lambda\gamma$ after differentiation. Equations (3) are those of the sections of the cubic and the polar quadrics of C and D by *any* plane through AB; and since they intersect in three coincident points at A, $m=12-3=9$.

The equation of a cubic having a binode B_4 at A is

$$\alpha\gamma\delta + \beta^2 v_1 + \beta v_2 + v_3 = 0 \qquad (4)$$

where v_n is a *binary* quantic in (γ, δ). Let $v'_n=dv_n/d\gamma$, $v''_n=dv_n/d\delta$. Differentiating (4) with respect to γ and δ, and eliminating α, we obtain

$$\left.\begin{array}{r} \beta^2(v_1-\gamma v'_1) + \beta(v_2-\gamma v'_2) + v_3-\gamma v'_3=0 \\ \beta^2(v_1-\delta v''_1) + \beta(v_2-\delta v''_2) + v_3-\delta v''_3=0 \end{array}\right\} \qquad (5)$$

The eliminant of (5) is a binary octavic in (γ, δ); whence B_4 reduces the class by 4.

The classes of all the remaining species may be found by means of the eliminant of (5), or directly from their equations.

September 6.

Ben Nevis Observatory and the Argentine Republic.

NEWS has reached me here from the office of the Scottish National Antarctic Expedition in Edinburgh of the appointment of almost the whole of the Ben Nevis Observatory staff to the Argentine Meteorological Office, including the superintendent, Mr. Angus Rankin, who has been associated with the observatory for more than twenty years, Mr. Robert Macdougal, for many years assistant, and Mr. Bee.

It may be remembered that in March, 1903, the Scottish National Antarctic Expedition set up a first-class meteorological and magnetical station in the South Orkneys, at Scotia Bay, and that, after the wintering of the *Scotia*, I offered to hand over the station, including Omond House and Copeland Observatory, to the Argentine Government with eighteen months' provisions, as well as to give a passage on board the *Scotia* to Argentine men of science if the Republic would undertake to continue the work and relieve the party the following year. This was carried through by the energy of Mr. Walter G. Davis, director of the Argentine Meteorological Office, and Mr. Robert C. Mossman, the Scottish expedition's meteorologist, was asked to continue in charge. Now Mr. Mossman has returned after two years' valuable work in the Antarctic, and the station is being kept up a third year—the first time in the history of Antarctic exploration that scientific observations have been carried on in one place for more than two years.

But the Republic is not satisfied; it is to continue the work for still another year, and is even going to increase the number of Antarctic stations. Trained men were required, and since Mr. Mossman's return he has been in communication with Mr. Davis, with the result that these three gentlemen have been appointed to carry on this work, as well as Mr. W. R. Bruce, also of Ben Nevis Observatory, who arrived in Buenos Aires three weeks ago.

The Argentine Republic must be congratulated on its enlightened perspective; but surely while doing so we must hang our heads in shame, for, while our Government has discouraged scientific research, we find this rapidly rising Republic eager to encourage it.

Properties of Photographic Plates Exposed to Light.

IN May, 1904, I exposed an ordinary sensitised ½ plate (20th Century Rapid) to daylight. It was so placed that the light had to pass through a window before falling upon the plate. The day was cloudy and dull, without sun, and the time of exposure was from two to four p.m.

In the meantime I placed an unexposed plate in a box, and upon it a steel pair of scissors. Then taking the exposed plate I placed it above the unexposed plate with the scissors in between and in contact with the sensitised sides of both plates.

After closing the box and wrapping up to exclude light, I put it away for six weeks.

At the end of this period I developed (with MQ) the unexposed plate, and found, as I had hoped, a radiograph of the scissors; then developing the exposed plate it appeared, if anything, to be less dark than the unexposed plate, but without any image.

During 1904 I repeated the experiment several times, varying the time of exposure and letting the light pass through thicker glass, also developing at shorter intervals, the days in every case being cloudy as in the first case. With one slight exception, I failed to obtain any result.

This year I put down three other pairs under the same conditions as the first experiment of 1904, but, if anything, the day, though cloudy, was much brighter. With these I obtained three good results, one of which I unfortunately spoilt in developing.

At present I have five or six other pairs which will be ready for development in four or five weeks' time. In these cases the day was bright sunshine, so that perhaps better results may be expected.

CAUSE AND PREVENTION OF DUST FROM AUTOMOBILES.

AT the present time by far the most serious problem which the automobilist has to face is the abatement of the "dust nuisance." A great deal of bad feeling has arisen against the motorist on account of the dust which he too frequently produces, and there is no doubt that there are very good grounds for the irritation which has arisen, more particularly in agricultural districts. Farming in this country, at the best of times, is not in a prosperous condition, and a farmer does not view with any kindly eye a further reduction in his produce through the effects of dust. Apart from that, however, dust may cause a great deal of personal discomfort to other users of the roads; but this phase of the question would, perhaps, not require very serious consideration were it not that dust of this nature is apt to carry disease, and to lower the health of the poorer part of our population living along the main thoroughfares. As such matters may lead to serious opposition to automobilism, and possibly to further legal restrictions, all tending to hamper a growing and very important industry in this country, it is becoming imperative to see what can be done to minimise a nuisance of this kind.

At present there are two distinct methods of tackling the problem. One is to treat the roads, or construct them, in some way so that they no longer give rise to dust. The other is to so alter the construction of the car that dust, if it exists, will not be raised to a serious extent. These two methods we will now consider.

(1) *Special Treatment of the Roads.*

Undoubtedly proper treatment of the roads, if something permanent and at the same time not costly could be devised, would be the most effective solution of the problem. If, for example, the surface could remain moist, there would obviously be no dust. But treatment with the ordinary watering-cart is very transient; moreover, it is destructive, for the water, as a rule, is used in excess. The use of a deliquescent substance, such as calcium chloride, naturally suggests itself. But in order to be effective the solution would have to be above a certain strength, and probably a little wet weather would remove so much of the deliquescent material that re-treatment would be necessary very soon.

A number of solutions are now on the market for the more or less temporary treatment of roads. Perhaps the best known is Westrumite, containing chiefly petroleum and ammonia, the product being completely miscible with water. It has been used extensively as a temporary measure. Experiments by the Scottish Automobile Club show that the effect remains for a considerable time. Three stretches of road, each about half a mile in length, comprising metalling in three different stages of wear, were selected. These were thoroughly cleaned and treated with a 10 per cent. solution of Westrumite. This was repeated after three days, and, as very heavy rain fell soon after, a solution of the same strength was applied a third time. The result appears to have been very satisfactory. Absolutely no dust was raised by vehicles of any description passing over the road for a very considerable time after the application, and even after three months the dust was nothing to speak of. On the metalling that had been worn the dust was found to be greater. The permanency of the result probably depends on the amount of traffic, as results elsewhere have not always been so satisfactory.

Other preparations of a similar character have

been devised, such as Akonia and Dustroyd. The latter is a liquid manufactured from tar, and as it is not soluble in water it should have the advantage of greater permanence, being less affected by rain than are soluble preparations. It is said to give an asphaltic surface to the roads.

A more permanent style of treatment is by means of oil. So far this method has not received much attention in this country, but in America it is being tried on an extensive scale. This is the case at Los Angeles, Cal. The secretary of the Chamber of Commerce of that city gives the following details in a report on the subject:—

"For the past four or five years the use of oil on our roadways has been increasing rapidly, and is now considered the best method for laying the dust, as well as of making a serviceable roadway. It has been taken up by the different boards of supervisors in the surrounding counties as well as by the superintendent of streets in Los Angeles, and we have now in the neighbourhood 300 or 400 miles of oiled roads within a radius of 60 miles of the city. It has been found, when properly applied and the necessary attention given to it, that it forms a smooth durable surface; and in one case of a road with a 6 per cent. grade treated with oil, it was found after a heavy rainstorm the road had not cut or washed, but on a road in the same neighbourhood under the same conditions not treated with oil it became impassable.

"The process of preparation varies considerably according to the opinions and experience of the different workers, as well as with the different material of which the road bed is composed. Some officials have claimed that a very sandy road would not be benefited with oil, but by repeated experiment it has been found that by putting on a very heavy coat of oil the loose sand has taken it up, and by continual application a very fair road bed has been made out of what was almost impassable sand. In some instances sandy roads have been first crowned up with a heavier soil or with clay, making a firm foundation, and then treated with oil, thus making as good a road as in other sections where the land is heavier. In some localities, where oil has been used for some time and careful attention given to repairs and renewal, the roads have become as smooth and hard as asphalt pavements and without the disadvantage of dust. In preparing an ordinary road, in some instances the surface has been loosened by a machine carrying something in the nature of a rake, for the purpose of being able thereby to mix the oil with the surface dirt. In others where the soil is heavy and packed hard, it has been covered with oil and then a thin coating of light sand is sprinkled over this, which causes the whole to cement together, forming a hard surface. For roads of this nature, that is, with a hard surface, it has been found preferable in many cases to use a light gravity oil, which is absorbed readily by the earth. In cases of light or sandy soil, it is contended by many that the heavier oils carrying more asphalt in their composition are more desirable and more effectual for the purpose.

"It is a hard matter to give any definite figures as to the cost of treating the roads, for the reason that conditions differ and prices of material vary in the different localities; but from the figures given by some of our supervisors it seems that it takes from 75 to 250 barrels of oil per mile for the first treatment, according to the character of the soil. About one-third of the original amount is sufficient for the second year, and thereafter in constantly decreasing amounts. It is stated that the average cost, taking the first application and the later attention, should not exceed 20*l.* per year per mile. It is authoritatively claimed that treatment by oil is much less expensive, even at the outset, than the use of water in laying the dust, and at the same time is enduring."

Mr. Lyle Rathbone, in a paper read before the Liverpool Self-propelled Traffic Association this year, gives an account of experiments with oil carried out on the roads at Liverpool. The oils used were hot and cold creosote oil by itself, creosote oil mixed with small proportions of pitch, resin, or tallow respectively, hot coal tar, cheap waste oil from coal tar, common petroleum, and crude Texas petroleum. The general results do not appear to be anything like so permanent as those obtained in America referred to above. They were satisfactory as far as they went, the tendency being for the road surfaces to be preserved, to dry more quickly, and to be cleaner. No very conclusive result as to the best oil seems to have been reached. Creosote oil with resin gave the cleanest and best appearance, and ordinary petroleum was the least lasting. Heavy coal tar waste oil lasted longer than creosote, and was very much cheaper; a single coat kept the surface in good order for about three weeks, and two coats for about five weeks.

Experiments by the Scottish Automobile Club showed that crude oil was most effective. It was poured on to the cleaned road surface by means of cans, and brushed over so as to saturate the surface uniformly. In about twelve hours the surface was dry enough for traffic. The cost per mile of road of fair average width was about 20*l.*, which may seem costly, but the method has the great advantage that a single application is sufficient for a season, and against this cost must be set a saving in other ways. It is to be hoped that more extensive experiments

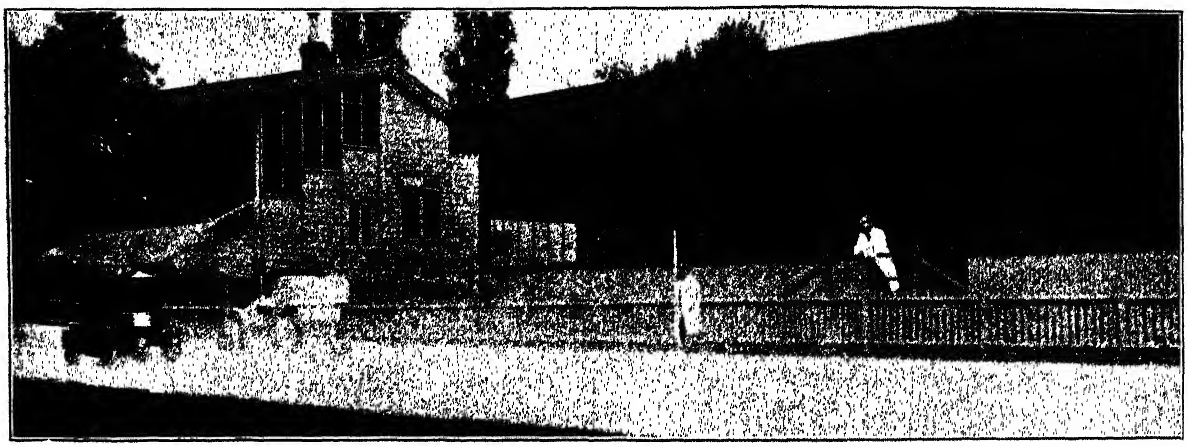

FIG. 1.—Test of a dustless car running over flour at the Crystal Palace. From the *Automobile Club Journal.*

will be carried out on these lines, for the results seem rather contradictory, and there are probably a good many factors to be observed.

In the methods so far referred to, attempts are made to improve the roads with their present mode of construction. But it would be more rational to use materials in road-making that would not give rise to dust; for example, with materials of a viscous nature. Tar very naturally suggests itself, and a good many experiments have been made either by mixing it with road materials or by applying it hot as a coating. Mr. Scott Montagu, in a paper recently read before the Automobile Club, gives several instances in which the tarring of roads has proved effective. It is perhaps a little early to say whether this treatment remains satisfactory under all conditions, or whether it may after a time give rise to unpleasant mud in wet weather under certain conditions.

In order to obtain a permanent result it seems necessary that the crust of the roadway should be really waterproof to a fair depth, so that dust-forming materials cannot work up. This result can only be obtained by combining the tar with the materials used in construction. It is useless, however, to tar such materials as granite or syenite, because the tar remains only on the outside, and as the material is worn the tar becomes ineffective. For that reason Mr. E. P. Hooley uses furnace slag, which is very porous, and produces a material which he has named "Tarmac." The slag is taken hot from the furnaces, broken, and thrown into tanks of tar. Upon cooling, the tar becomes absorbed, and the slag is thoroughly impregnated, so that if the pieces are broken further a tarred surface is still found. In other words, the material is such that it cannot give rise to dust. It is used in construction, like other materials, to a depth of several inches. The initial cost is rather heavier than for a macadam road, but this appears to be more than counterbalanced by the greater durability and the fact that a waterproof road is obtained free from dust and requiring much less cleaning than the usual macadam.

FIG. 2.—Test of a dusty car running over flour at the Crystal Palace. From the *Automobile Club Journal.*

(2) *Design of the Car.*

Although a permanently good road may be made by the use of such materials as Tarmac, and dusty roads may be cured temporarily by various means, yet such measures can be taken only over a small proportion of our roads owing to the cost. In towns and large villages the roads might be suitably treated; but the average motorist seeks the country, and the greater part of the routes which he wishes to traverse will not pay for any special treatment. It therefore becomes very important to modify the design of cars so that the dust raised may be reduced to a minimum, and also, if possible, to find some simple means of checking the dust in the case of cars already in use.

One of the simplest defects to remedy is the direction of the exhaust, which is sometimes pointed downwards. In such a case the dust raised by the exhaust alone may be considerable, and an improvement may be made very simply. It has even been proposed to use the exhaust, suitably directed, for laying the dust which is otherwise raised by the car; and M. Baudry de Saunier, editor of *La Vie Automobile,* vouches for the efficiency of the Feugère system, as it is called. The exhaust is discharged from a horizontal pipe taken across the back of the car, having a line of holes along its length. Thus a number of jets in the same plane is formed, and the pipe is so mounted that the angle at which these jets impinge on the roadway may be varied so as to be as effective as possible. Naturally, the less fluctuating the stream of exhaust gases the better for such a purpose, and the result is said to have been much more satisfactory on a four-cylinder than on a single-cylinder car. I have not had an opportunity of seeing this device in action.

Speaking generally, and leaving such special points as direction of exhaust out of account, it may be said that the dust is raised by the tyres, and is then scattered by the air currents produced by the body. In other words, if the body were moved along the road at its normal height, supported by other means than the wheels, very little dust would result. But it is equally true that if the wheels could be run without the body there would not be much cause for complaint as to dust. By *body* is here meant the whole structure, apart from the wheels, so that the term is more comprehensive than usual. The passage of a car body through the air necessarily creates a great deal of disturbance, and the extent to which the air near the ground is disturbed must depend to a great extent upon the shape of the body. The less the disturbance, the less will the dust be formed into a cloud.

In 1903, the Automobile Club tested the dust-raising qualities of a large number of cars. Each car was run at twenty miles per hour over a patch of flour on the cycle track at the Crystal Palace. The flour was kept at a definite thickness, and as each car passed it was photographed. These photographs gave a permanent record of the dust cloud raised by each car, enabling the committee to classify the cars in the order of merit. The records so obtained gave a great deal of useful information, and it was recognised that this method of testing was far more satisfactory than optical observations, because an observer has a good deal of difficulty in retaining a mental picture of what may be termed a standard car as regards dust.

In a paper read in 1903 before the Automobile Club, Colonel Crompton and Mr. Crawley came to the following conclusions, based on these experiments:—Hard tyres are better than soft; narrow tyres are better than broad; neither have a preponderating influence; flaring mud-guards are probably bad, especially if they come low down; cars which are low underneath are worse than cars a long way off the ground; but smoothness of bottom-shape and absence of forward coning are infinitely more important. There is strong evidence that it is desirable that the car should slope upwards towards the back. At the same time, the authors point out that "a low car is not necessarily a dusty one, nor is a high car necessarily dustless."

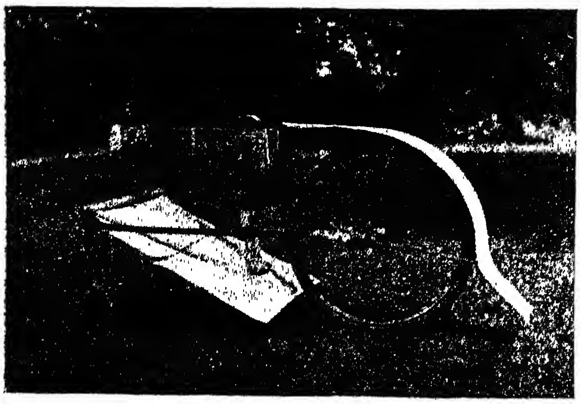

FIG. 3.—Experimental tricycle.

Figs. 1 and 2, which are reproductions of photographs taken during the Crystal Palace tests, show the great difference that already exists between different makes of car, the first being of a comparatively dustless car, and the second of a very dusty car, both running at twenty miles per hour, the pace being given by a "speed car" running alongside. It will be seen that it is possible to make cars comparatively dustless, though the means of doing so are not yet well understood.

In approaching the problem, it is necessary to give up all preconceived ideas, for the practical results by no means always agree with what would theoretically be expected. If a dusty car and a comparatively dustless car are examined and compared, it is often not at all easy to say why the one is more dusty than the other. People are apt to have the idea that comparatively small differences in the car body are important. Last year, however, the Automobile Club carried out a series of experiments on different shapes of body, and these showed that the dust raised did not depend to any great extent upon the shape, at least as regards small modifications of the upper structure. An irregular shape under the chassis is no doubt bad, and the transverse tool-box carried low down at the back of the car, which is frequently seen, is certainly harmful.

The investigation of the problem by means of a car is difficult, owing to the number of variables. For example, the experimental car may be a "medium" dust-raiser, and, if any modification is made, the effect may be masked to a considerable extent by other factors which we may not be able to control. Therefore it would be better, if possible, to study the problem with a much simpler apparatus, so that any one variable might be taken in turn without difficulty. In the hope of doing something in this way, I have recently carried out experiments on an elementary form of tricycle, which is shown in Fig. 3. This is drawn over a track laid with

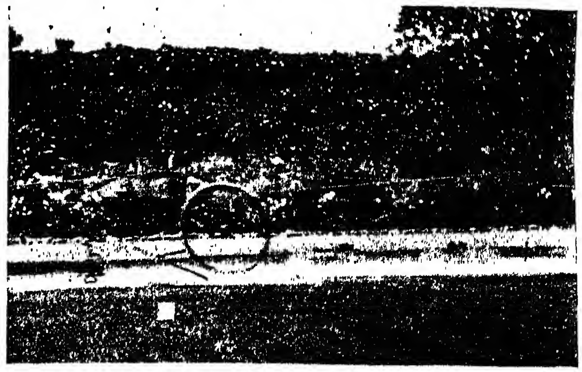

FIG. 4.—Dust thrown up by a tyre pumped hard.

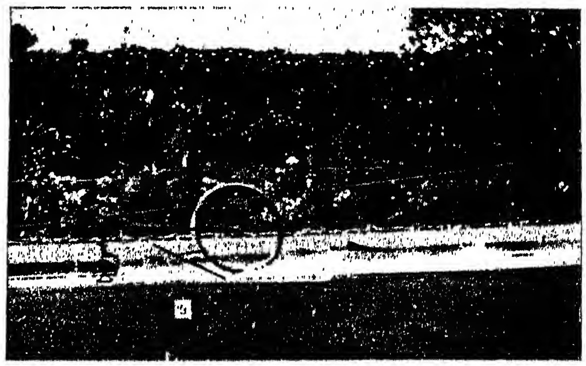

FIG. 5.—Dust thrown up by a very soft tyre.

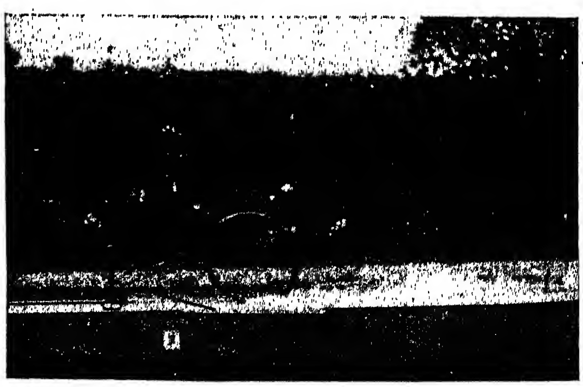

FIG. 6.—Dust thrown up by a very soft tyre loaded with 12 lbs.

flour at, say, fifteen to twenty miles per hour, and photographs are automatically taken to show how much dust is raised by the large wheel, which is an ordinary bicycle wheel. The flour is laid only along the centre of the track, so that the bicycle wheel is the only one that causes any disturbance. As the framework is of very simple construction, it may be regarded as causing no serious disturbance in the air, unless it is supplemented by some form of body. In the illustration it is shown provided with a mud-guard and an inclined plane; these, and any other "bodies," are easily made of cardboard, and a number of experiments can be carried out in a comparatively short time.

By stripping the frame, the action of the tyre alone, apart from any body, may be easily investigated in a way which is impossible with a car having four wheels with a conflicting set of mud-guards, or a body which will affect the back wheels quite differently from the front wheels. Thus Fig. 4 shows the dust thrown up by a tyre pumped hard, from

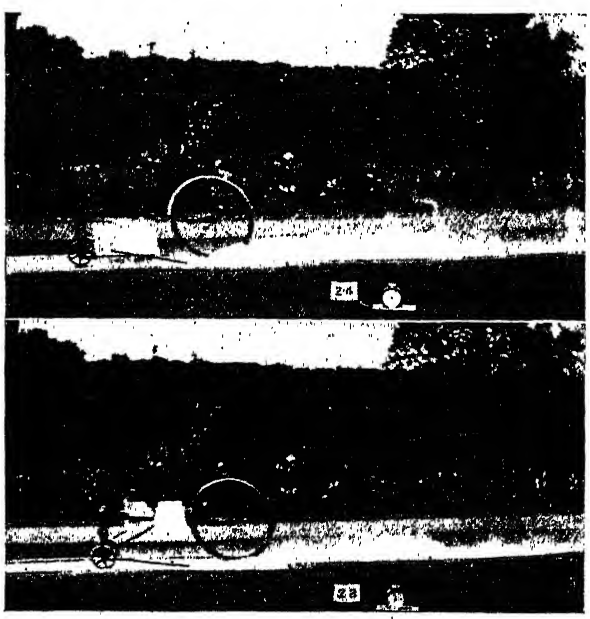

FIG. 7.—Dust cloud formed by a square box 3 inches off the ground.
FIG. 8.—Dust cloud formed by a square box 9 inches off the ground.

which it will be seen that the dust is only slight. In Fig. 5 the effect is shown of a very soft tyre, the dust being a good deal more. In both these photographs the tyre was unloaded, except for the proportion of the frame which it had to bear. But in Fig. 6 the effect is shown of a load of 12 lb. on the tyre, and it is seen that the dust raised is much increased.

Although, from the point of view of raising dust, the tyres may not be so important as the body, their action does seem to be important enough to warrant more careful investigation. They are capable, in themselves, of raising a good deal of dust, as is often to be seen in the case of bicycles. Very possibly dust is carried up by tyres through a kind of suction, and this may vary a good deal with the design. Now that there are so many different tyres, including non-skidding bands, on the market, there is likely to be a considerable difference in the various types as regards dust. In the photographs which are reproduced, the wheel is equivalent to the front wheels of a car, as there is no driving force on the tyre. In the case of wheels which are drivers, there will be a certain amount of slip of one kind or another, and the dust raised is likely to be greater; but, actually, there

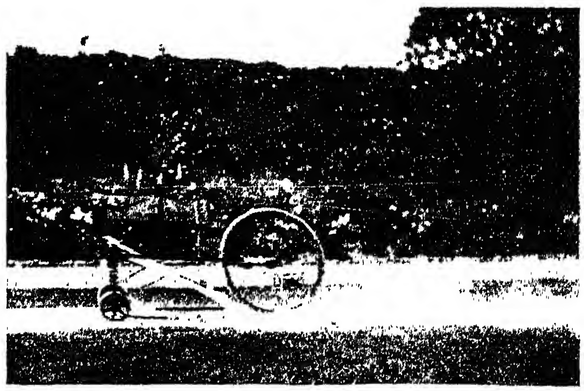

FIG. 9.—Effect of an inclined plane.

does not seem to be any very great difference between drivers and non-drivers—at least there is much less than would be expected.

As regards "bodies," Figs. 7 and 8 show the effect of allowing a square box, 18 inches long by 20 inches wide and 12 inches deep, to precede the wheel. In Fig. 7, which shows a large cloud of dust, the box is only 3 inches off the ground; but in Fig. 8 it is 9 inches above the ground. In the latter there is still a lot of disturbance, which fact is of interest, seeing that the bodies of certain cars are brought down to within about 6 inches of the ground. These illustrations and those following are comparable with Fig. 6, the tyre being loaded and soft, and the motion being always from right to left. In Fig. 9 is seen the effect of an inclined plane, so inclined that the air is severely thrown down on to the track. It is a little surprising to notice that the effect of the plane is not nearly so serious as that of the box seen in the two preceding illustrations, although the box and plane are about the same in width, and the plane, which is carried down to within about 4 inches of the ground, is of considerable length. It may be, therefore, that the inclination of the under surface of a car body is not of much importance after all. In Fig. 10 is shown the very marked disturbance caused by a vertical card, 12 inches square, fixed

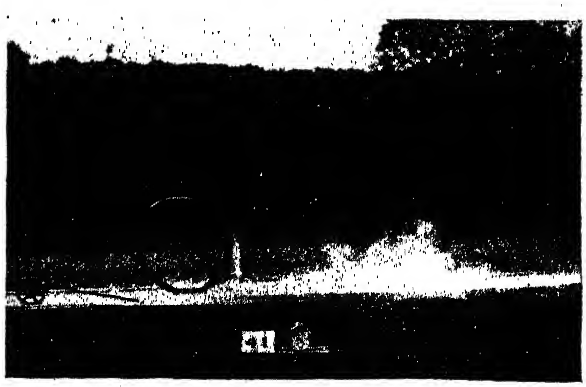

FIG. 10.—Effect of a vertical plane behind the wheel.

behind the wheel; this is akin to the tool-box which is often carried low down behind a car, and is generally recognised as having a bad effect.

In the present article it is impossible to go further into details. The apparatus as illustrated is rather crude and elementary, but I think enough has been said to justify the view that a good deal of useful work might be done by working with apparatus on these lines.

W. R. COOPER.

THE INTERNATIONAL UNION FOR COOPERATION IN SOLAR RESEARCH.

A CONFERENCE of the International Union for Cooperation in Solar Research will be held on September 27 at New College, Oxford, by invitation of the warden and fellows of the college. The following delegates of societies constituting the union have signified their intention of being present:—

From the United States, Profs. Hale and Campbell; from France, Messrs. Janssen, Deslandres, Fabry, Perot, and the Comte de la Baume Pluvinel; from Russia, M. Belopolski; from Germany, Prof. H. Kayser; from Holland, Prof. H. H. Julius; from Sweden, Prof. Knut Ångström; from Switzerland, Prof. A. Wolfer; from Austria, as representative of the International Association of Academies, Prof. Edmund Weiss. Great Britain will be represented by Profs. Turner, Schuster, and Fowler, Father Cortie, Mr. W. E. Wilson, Major Hills, Dr. W. J. S. Lockyer, and Dr. Halm. The subjects of discussion will include the following:—

The fixing of standards of wave-length in spectroscopic research, cooperation in the measurement of the intensity of solar radiation, cooperation in recording solar phenomena by means of photographs of the disc, spectroheliograph records and observations at the limb of the sun.

The foreign savants will be lodged at and entertained by New College. On Friday, September 29, the president of the Astronomical Society and Mrs. Maw will give a reception at their residence in London, and for the following day invitations to visit the observatories at Cambridge have been received from Sir Robert Ball and Mr. Newall. Prof. Schuster is acting as chairman of the executive committee which was appointed last year at the first conference of the union held at St. Louis.

NOTES.

THE meeting of the International Meteorological Conference at Innsbruck was opened on Saturday last, September 9, and the full sittings began on Monday. The following is a list of members attending the conference:—F. Åckerblom, Upsala; Rev. P. J. Algué, S.J., Manila; A. Angot, Paris; R. Assmann, Lindenberg bei Breskow; A. Belar, Laibach; W. v. Bezold, Berlin; B. Brunhes, Puy de Dôme; V. Carlheim-Gyllensköld, Stockholm; V. Conrad, Vienna; P. M. Dechevrens, Jersey; E. Durand-Gréville, Mentone; Sir John Eliot, London; F. Erk, Munich; E. van Everdingen, de Bilt; G. Fineman, Stockholm; Rev. P. L. Froc, S.J., Zi-ka-wei; V. Gama, Tacubaya Obs., Mexico; G. Greim, Darmstadt; J. Hann, Vienna; G. Hellmann, Berlin; E. Hepites, Bukarest; H. Hergesell, Strassburg; H. H. Hildebrandsson, Upsala; W. Kesslitz, Pola; N. v. Konkoly, Budapest; W. Köppen, Hamburg; A. Lancaster, Uccle; W. Láska, Lemberg; E. Lauda, Vienna; J. Liznar, Vienna; Sir N. Lockyer, London; W. J. S. Lockyer, London; J. H. Lyons, Cairo; E. Mazelle, Triest; H. Mohn, Christiania; A. Mohorovičić, Agram; L. Moore, Washington; M. Nedelkovitch, Belgrade; L. Palazzo, Rome; A. Paulsen, Copenhagen; J. M. Pernter, Vienna; F. C. A. Pockels, Heidelberg; P. Polis, Aachen; G. B. Rizzo, Messina; A. L. Rotch, Boston; P. v. Rudzki, Cracow; M. Rykatchew, Petersburg; A. Schmidt, Potsdam; A. Schmidt, Stuttgart; P. Schreiber, Dresden; Ch. Schultheiss, Karlsruhe; Rev. P. Th. Schwarz, Kremsmünster; W. N. Shaw, London; A. Silvado, Rio de Janeiro; R. F. Stupart, Toronto; L. Teisserenc de Bort, Trappes; W. Trabert, Innsbruck; J. Valentin, Vienna; J. Violle, Paris. The members of the Solar Commission are:—M. Angot, Sir John Eliot, Prof. Hann, Sir N. Lockyer (president), Dr. Lockyer, Captain Lyons, Prof. Pernter, Prof. Rizzo, Dr. Rotch, Dr. Shaw, M. Teisserenc de Bort, Dr. Konkoly.

THE Carnegie Institution, Washington, sent Profs. F. Elster and H. Geitel and Herr F. Harms to Palma to make observations of the electric conditions of the atmosphere during the recent solar eclipse. By means of a self-registering electrometer, the variation of atmospheric electricity was photographically recorded, and a series of points of the same curve was taken simultaneously by eye-readings. The ionisation of the air was studied by a "Zerstreuungsapparat," and also by an "Ebert's Föncounter." Besides these observations, exact measurements of the intensity of the solar radiation within the short wave-lengths were carried out, a peculiar kind of photometer having been prepared for this purpose. It is based upon the property possessed by clean surfaces of the alkaline metals of emitting kathode rays of a density proportional to the intensity of the incident light; by these rays the small residue of gas contained in a vacuum glass bulb is rendered conductive, and a circuit of a current is closed, the intensity of which may be read by means of a d'Arsonval galvanometer. In the apparatus alluded to the sensitive surface consisted of a thin layer of pure rubidium metal. An accuracy of ½ per cent. to 1 per cent. was easily obtained. By a blue Jena glass rays of long wavelength are absorbed before reaching the rubidium surface, so only the blue and violet, and partially the ultra-violet, region of the spectrum remains, and these are the radiations which may be supposed to have an ionising effect on the atmospheric air. The results, as well as the description of the apparatus, will be published in the reports of the Carnegie Institution. Unfortunately the observations, like all others in Spain, suffered from the bad weather conditions. On the day of the eclipse rain fell during the morning; consequently it cannot be considered as undisturbed with regard to atmospheric electricity. The measurements of the solar radiation were possible in a continuous series only from the first contact to the end of totality; the decrease of illumination, therefore, was determined in a satisfactory manner and without any gaps. On the other hand, clouds prevented any reading being taken during the increase of light after totality.

THE photographs of the total solar eclipse, taken by the Solar Physics Observatory Expedition at Palma, have proved to be better than was expected from the state of the sky during totality. A fine picture of the corona was secured with the long-focus mirror, but the clouds were too dense for successful tri-colour photographs to be obtained.

THE visit of the members of the British Association to the Victoria Falls on September 12 was made the occasion of the formal opening of the bridge over the falls, by Prof. G. H. Darwin, president of the association. In declaring the bridge open, Reuter's Agency reports Prof. Darwin to have remarked that the great enterprise of the Cape to Cairo Railway, of which the bridge is a part, had

become possible by the influence of steam. He could not refrain from quoting the remarkable forecast written by his great grandfather, Erasmus Darwin, in 1785:—

> Soon shall they arm unconquered steam afar,
> Urge the slow barge and draw the flying car.

How little could the writer of these lines have foreseen that his great grandson would have the honour of declaring a railway bridge open in the heart of Equatorial Africa. Yet another interesting point was that this enterprise had rendered possible a purely scientific enterprise. He referred to the great survey of an arc of meridian which was due to the insight of Sir David Gill.

IT is announced that the Emperor of Austria has made Dr. Karl Toldt, professor of anatomy in the University of Vienna, a life member of the Austrian House of Lords.

THE Harben lectures will be delivered in the lecture room of the Royal Institute of Public Health on October 10, 12, and 17 by Prof. T. Oliver. The subject of the lectures will be some of the maladies caused by the air breathed in the home, the factory, and the mine, including a description of caisson disease or compressed air illness.

A TELEGRAM to the *New York Sun* from Honolulu states that the steamship *Sierra*, which arrived at New York on September 6 from Australia, reports that a volcanic eruption has occurred on the island of Savaii, the largest of the Samoan group.

THE Arctic expedition of the Duc d'Orléans arrived at Ostend on September 12 on board the *Belgica*. M. de Gerlache, the commander of the expedition, said that the duke and himself were delighted with the results attained. They had been able to follow the pack ice the whole way from Spitsbergen to Greenland. The expedition has brought back a number of cases containing collections of scientific value.

WE regret to have to record the death of Mr. H. R. Noble, a past student in physics at University College, London. Mr. Noble had shown the possession of great experimental ability in connection with various investigations published by the Royal Society, especially by his work on the question of the relative movement of ether and matter. He had gained an 1851 scholarship, and had gone to Giessen to work under Dr. Drude when failing health compelled him to relinquish this work. Mr. Noble was very popular amongst his fellow-students and teachers at University College, and the news of his early death will be received with great regret.

IT was stated recently by the *British Medical Journal* that a member of the Brazilian Chamber of Deputies had proposed that a prize of 400,000*l*. should be offered for the discovery of a certain method of stamping out consumption. It is now understood by our contemporary that the offer, which has been approved by the Brazilian Parliament, is larger in scope than was supposed, for it appears that the prize will be given to anyone, native or foreign, who shall discover a certain means of prevention or cure of syphilis, tuberculosis, or cancer. The Brazilian Minister of the Interior will, it is said, refer the proposal to a committee composed of a representative of the National Academy of Medicine, and four other members of kindred bodies in France, England, Germany, and Italy. The Brazilian Government will regulate the meetings of the committee.

THE Paris correspondent of the *Times* states that one of the most interesting features of the International Congress on Tuberculosis, to be held at the Grand Palais on October 2–7, will be a museum and international exhibition of tuberculosis. The Paris Municipal Council has agreed to retain a considerable part of the scientific objects in the exhibition for a permanent free museum similar to that established by the Berlin Municipality at Charlottenburg. The opening meeting of the congress will be presided over by the President of the Republic, and attended by numerous French and foreign delegates, including leading men of science. The congress will be divided into four sections, that of medical pathology being presided over by Prof. Bouchard, that of surgical pathology by Prof. Lannelongue, that of the preservation and assistance of infant life by Prof. Grancher, while that of the preservation and assistance of adult life and social hygiene will be under the joint presidency of Prof. Landouzy and Senator Paul Strauss. The acting president and vice-presidents of the congress are Dr. Hérard, of the Academy of Medicine, and Profs. Chauveau and Brouardel, of the Institut de France. Dr. C. Theodore Williams and Dr. H. T. Bulstrode have been appointed by the Government the British delegates to the congress.

A SEVERE earthquake disturbed a large part of Italy and Sicily on September 8, causing much damage and the loss of hundreds of lives. The region most affected was in the vicinity of Monteleone, Calabria. The shock caused damage so far as Sant Agata di Saro, Roggiano, and Gravigna (province of Cosenza) and Sicily in the south, and there was a sensible seismic movement in the north so far as the province of Palermo, Saserno, Basilicata, Puglia, Bari, and Lecce, and in the south over the whole eastern coast of Sicily. The following summary of Reuter's messages contains the essential facts relating to the disturbance:—*Reggio, Calabria, September* 8.—Very severe earthquake at 2.44 a.m. *September* 9.—Two undulating earthquake shocks of short duration felt at 2.8 p.m. *Catanzaro, Calabria, September* 8.—Violent shock of earthquake, lasting eighteen seconds, felt at 2.55 a.m. Several walls collapsed and cracks appeared in others. *Messina, September* 8.—Very severe shock occurred at 2.43 a.m., the direction of movement being from north to south. *Rome, September* 8.—Shock felt about 2.45 a.m., followed by other shocks during the day. Public clocks stopped. *September* 9, 2 p.m.—Slight shock registered by the instruments of the observatory at Rocca di Pappa. *Martirano.*—Many killed and injured. All the buildings collapsed. *Stefanaconi.*—Many houses destroyed, and about 100 people killed. *Piscopio.*—Every house in the village in ruins, and the dead number 50. *Monteleone.*—Many houses destroyed, and about 600 lives lost in the district. *Triparni.*—Totally destroyed, and 60 people killed. *San Gregorio.*—Sixty-five deaths. *Zammaro.*—Houses destroyed. *Zungri.*—Nearly every house wrecked, and many persons killed. *Cessaniti.*—Practically all the houses destroyed. *Bratico, Sanleo, St. Costantino,* and *Conidini* totally destroyed. *Catanzaro.*—All the villages in this province seriously damaged. Several entirely destroyed. About 450 killed and 1000 injured. *San Floro.*—Houses seriously damaged. *Daffina, Daffinillo,* and *Louzione, in the district of Tropea.*—Much damage done to houses. *Fesenza.*—Shock very severe, and extensive damage done. *Syracuse* and *Catania.*—Severe shocks felt. *Castellammare, Naples,* and *Florence.*—Slight shocks.

AN article in the *Hong Kong Daily Press* by Mr. W. Kingsmill discusses the position of Ophir. He argues that the situation of Ophir and the provenance of the gold of Ophir are two distinct questions, holding with Prof. Keane that the latter came from South Africa; the

ruined cities of which are engaging the attention of the British Association and, what is more to the purpose, of trained archæologists. The original Ophir, on the other hand, Mr. Kingsmill locates at the head of the Persian Gulf, which was reached by Solomon's fleets; he makes his argument depend to some extent on a second argument to prove that the head of the gulf is the site of the Garden of Eden—a theory not improbable in itself, but apparently unconnected with the question of Ophir and the source of Solomon's treasure or of that of the earliest civilisations. Mr. Kingsmill has no evidence to show that the Jews connected the Garden of Eden with the head of the Persian Gulf, even if the myth originally referred to that area, and it is by no means clear why the Jews should associate gold with Ophir when they were, in Mr. Kingsmill's opinion, drawing their supplies of that metal from South Africa; for no evidence is produced to show that they drew gold from Mr. Kingsmill's Ophir at any time, or yet that the head of the Persian Gulf was known, much less proverbial in pre-Solomonic times as a source of gold. Mr. Kingsmill holds that Ophir, Sheba, Sofala, Havilah, &c., are one and the same, but it is scarcely sufficient to urge in proof of this that York appears twenty times in the *Times* Atlas. Needless to say, the article was written without knowing Mr. Randall MacIver's results recently described.

THE issue of the *Electrician* for September 1 contains a note by Lieut. Evans, R.E., upon some experiments made with different methods of earth connection for wireless telegraphic installations. The experiments were made with an oscillator consisting of a square copper wire capacity, 17 feet square, suspended horizontally by insulators, 14 feet above the ground. From the centre of this area, a vertical wire led to one knob of a spark gap, the other knob being connected by a similar wire to an iron-wire netting 17 feet square, suspended horizontally 2 feet above the ground, also on insulators. The current flowing in the vertical wire was measured under various conditions as regards the earthing of the iron-wire netting, and it was found that any connection of the transmitter or of the receiver with the earth was objectionable, since it greatly reduced the current flowing in the vertical wire. The most desirable form for the oscillator was, in fact, proved to be that approaching closely to a symmetrical Hertz oscillator as described by Sir Oliver Lodge in his Patent Specification, No. 11,575, of 1897. In this specification, two capacity areas, connected by self-induction coils and the receiving transformer, are clearly indicated.

As is customary, the issues of the *Lancet* and the *British Medical Journal* for September 2 are students' and educational numbers dealing with the curriculum necessary for the student of medicine, the various medical schools, books, the portals of entry into the profession, &c. The guardian of a prospective student could not do better than consult these periodicals.

THE issue of *Biologisches Centralblatt* for August 15 contains an article by Mr. A. Issakowitsch on the causes of sexual determination in water-fleas of the daphnid group, and a second by Prof. J. Lebedensky on the embryonic development of the echinoderm *Pedicellina echinata*.

FISHES from Borneo, principally from the Baram district of Sarawak, form the subject of a paper by H. W. Fowler in the July issue of the *Proceedings of the Philadelphia Academy*. Several are described as new, notably a shark belonging to the "tope" group, referred to the genus Carcharinus as *C. tephroides*.

IN a recent issue of *Science* Mr. O. A. Peterson, of the Carnegie Museum, publishes a preliminary note on remains of a huge pig-like animal allied to Entelodon from the Loup-Fork beds of Nebraska, for which the name *Dinochoerus hollandi* is suggested. The chief grounds for generic separation of the new form appear to be the geological horizon and the immense proportions of the animal, of which the skull measures no less than thirty-five inches in length. It would be interesting to ascertain what relation this monster presents to the imperfectly known Tetraconodon of the Indian Siwaliks.

THE *Fortnightly Review* and the *Independent Review* for September each publish articles on the origin of life. In the former Mr. Burke gives an account of his experiments in which, by the action of radium on bouillon, microscopic bodies, termed "radiobes," appear. These seem to divide by fission, like a micro-organism, and not by cleavage, as obtains in a crystal. Mr. Burke concludes that the continuity of structure, assimilation, and growth, and then subdivision, together with the nucleated structure as shown in a few of the best specimens (of radiobes), suggests that they are entitled to be classed amongst living things, in the sense in which we use the words, whether we call them bacteria or not. In the *Independent Review* Dr. Charlton Bastian writes on the origin and development of living matter on the earth, and discusses his theories of archebiosis and heterogenesis. With regard to the former, the formation of living matter by a process of synthesis from its primitive elements, Dr. Bastian recognises the extreme difficulty of proving it, and suggests that when the results are negative in a "sterile" fluid this may be due to the degrading influence on the fluid of the heat employed for sterilisation. But "sterile" nutrient fluids, *e.g.* egg-white and blood-serum, may be obtained without the use of any treatment. As regards heterogenesis, the development of one form of living matter into another, *e.g.* amœbæ from a bacterial zooglœa, bacteriologists will not accept this until it has been proved that the germs of the species which is supposed to have developed were not present in the original zooglœa.

THE London County Council has issued an admirable little handbook (price 1*d.*) to the case in the Horniman Museum, Forest Hill, arranged as an introduction to the study of birds' eggs. It is illustrated by six reproductions from photographs of specimens in the case intended to show variation in colouring, protective coloration, the numbers in clutches of different species, size as compared to that of the parent, form, and grain of the shell. The first two plates require, of course, to be coloured in order to bring out the distinctive features of the specimens, but this would probably have involved too great expense.

IN the report of the Manchester Museum of Owens College for 1904–5, an appeal is made to the public for aid in preventing its work and expansion being crippled for want of funds. The most important event recorded during the year under review is the presentation by Mr. J. Haworth of his collection of Egyptian antiquities, which contains a large proportion of the specimens obtained by Prof. Flinders Petrie between the years 1888 and 1897. The museum has issued as one of its handbooks the second and third parts of Mr. H. Bolton's paper on the palæontology of the Lancashire Coal-measures, originally published in the *Transactions of the Manchester Geological and Mining Society* for 1904.

IT is satisfactory to learn from *Science* that Trinity College, Connecticut, has made arrangements for establishing a floating laboratory of marine biology for the purposes

of explorations in oceanography, collecting specimens, and supplying teaching and scientific institutions with material for the study of marine organisms. A suitably fitted vessel of about 90 tons will be dispatched next summer for the Bahamas. In connection with this announcement, we may refer to a communication from Prof. M. E. Henriksen, of Ohio University, published in *Biologisches Centralblatt* of August 15, with reference to a proposal for the establishment of a biological station in Greenland, which, it is urged, would be sure to yield results of great scientific importance. "Back to nature" is the cry of the writer, who insists that biological progress now depends upon the observation of the relationship of organisms to their environment rather than on microscopic work in the laboratory.

EVER since the 'fifties, when the late Dr. H. Falconer wrote a note on the subject, strenuous efforts have been made to discover the origin of the so-called "bee-hole borings" which ruin the heart-wood of so much Burmese teak timber. Mr. E. P. Stebbing, who has been fortunate enough to discover the insect causing this serious damage, has recorded, albeit in a somewhat prolix manner, his investigations which led up to the discovery in a pamphlet published by the Calcutta Government Press under the title of "The 'Bee-hole' Borer of Teak in Burma." The offender turns out to be the larva of a large moth, which, after living for some time in the bark, when about to pupate bores large channels right into the heart-wood of saplings. As the sapling grows into a tree the borings remain in the heart, and thus completely ruin the timber for many purposes. Suggestions are made with regard to remedial measures.

THREE out of the four biological papers in the issue of the *Journal of the Straits Branch of the Royal Asiatic Society* for July are by H. N. Ridley, director of the Singapore Botanical Gardens, and relate to botanical subjects. In the first the author discusses the Gesneraceæ of the Malay Peninsula, and in the second the aroids of Borneo, while in the third he continues his descriptions of new and little known Malay plants. In the one zoological paper Mr. P. Cameron publishes a third contribution to our knowledge of the Hymenoptera of Sarawak. Among short notes, Mr. H. C. Robinson, of the Selangor Museum, records from the district where he is stationed that rare mammal the pen-tailed tree-shrew (*Ptilocercus lowei*), hitherto known only from Borneo.

THE flowering of bamboos, which a short time ago formed the subject of correspondence in NATURE, is discussed in a short article by Prof. F. A. Forel in the *Gazette de Lausanne* (August 1). In the spring a general flowering of the plants of *Bambusa gracilis,* a garden variety, took place at Morges, Canton Vaud, and flowering was observed at Nyon, Territet, Versoix, and Bex. The writer raises the questions whether the flowering is due to inherent causes or dependent upon climatic conditions, whether the seed produced is fertile, and whether all the plants die after flowering, and he requests that observations on these and similar points may be forwarded to him at the University of Lausanne.

WE have received the tenth volume of Dr. Otto Baschin's "Bibliotheca Geographica," dealing with the year 1901. The volume shows no specially new features, a certain advantage in publications of the kind, and it maintains the fulness and accuracy of its predecessors.

IN view of recent proposals to "utilise" Lake Titicaca, a paper on the basin of that lake, contributed by Mr. A. F. Bandelier to the August number of the Bulletin of the American Geographical Society, is of more than usual interest. Mr. J. Russell Smith publishes a paper on the economic importance of the plateaux in tropic America in the same number, which also contains a well illustrated mountaineering paper on the Alaskan Range by Mr. Alfred H. Brooks.

AN elaborate memoir on the commercial significance of the Suez Canal, by the late Herr Martin Voss, appears in the *Abhandlungen* of the Vienna Geographical Society. Herr Voss's paper contains much statistical and other information in small compass, and should be extremely useful, especially if studied in relation to Ungard's work on the same subject, recently published in Vienna. Herr W. Schjerning contributes to the same publication a paper on the equidistant projections used in cartography.

A DESCRIPTION of a new apparatus for demonstrating the elementary principles of mathematical geography is given by Dr. Hermann v. Graber in *Petermann's Mitteilungen.* The fundamental idea is the application of the orthogonal projection to the ordinary wire model or "tellurium," hence the name "orthogonal-tellurium." Besides being available for teaching purposes, the instrument affords the means of making angular measurements with sufficient accuracy to be of use for rough work in the field.

THE scorification assay for gold telluride ores has long been believed to give low results by reason of volatilisation, and it is now seldom used for ores of that class, the assay by crucible being supposed to be more trustworthy. The results of a careful investigation of the subject by Mr. W. F. Hillebrand and Mr. E. T. Allen, published in Bulletin No. 253 of the United States Geological Survey, show that the doubts entertained as to the accuracy of the dry method are not well founded. There is no reason to question the substantial accuracy of the crucible method. Indeed, it is clearly established that the fire assay by crucible for gold telluride ores gives results which are quite equal to those obtained by the wet way, provided due corrections are made for slag and cupel losses. The gold loss in the slag is very small, but the cupel losses are considerable, the cupellation loss of gold by volatilisation being small as compared with that by absorption.

THE Cripple Creek gold deposits in Colorado were discovered in 1891, and up to 1904 yielded 124,415,022 dollars of gold and 646,193 ounces of silver. The district was surveyed for the United States Geological Survey in 1894 by Messrs. W. Cross and R. A. F. Penrose, and at the request and at the cost of the State of Colorado it has now been re-surveyed by Messrs. W. Lindgren and F. L. Ransome, and a summary of the facts of immediate importance has been published (Bulletin No. 254). There are some 300 mines in the district, and every accessible one was examined. The deepest shaft is the Lillie, which is more than 1500 feet deep; and the productive district is covered by the area of a circle 3½ miles in diameter. An interesting feature of the ore-deposits is the occurrence of gas which in some cases issues in large volumes. Analysis shows it to consist of nitrogen, with about 20 per cent. of carbon dioxide and a small quantity of oxygen.

AT the St. Louis Exhibition last year an investigation of the coals and lignites of the United States was carried out under the direction of the director of the United States Geological Survey, the sum of 6000*l.* having been voted by Congress for the purpose. Testing machinery was generously contributed by various manufacturers, and much valuable work was done with the plant, such an elaborate series of coal analyses having never before been made in

the United States. The preliminary report on the operations of the plant, drawn up by Messrs. E. W. Parker, J. A. Holmes, and M. R. Campbell, the committee in charge, has been issued as Bulletin No. 261 of the United States Geological Survey, and is of far-reaching importance in the solution of the fuel and power problems upon which the varied industries of the United States depend. Most of the American bituminous coals and lignites can, it was found, be used as a source of power in a gas-producing plant, the power efficiency of bituminous coals when thus used being $2\frac{1}{2}$ times greater than their efficiency when used in a steam-boiler plant. Some of the lignites from undeveloped but extensive deposits in North Dakota and Texas showed unexpectedly high power-producing qualities. It was found, too, that some of the American coals and the slack produced in mining them could be made into briquettes on a commercial basis.

THE weather over the British Islands has been very unsettled during most part of the last week, rainfall being very prevalent generally; in the south of England and all the western districts the amount was much above the average. Strong gales occurred in many places, especially on the western and southern coasts, and the sea has been very rough at times. The Meteorological Office reports on Tuesday showed a considerable improvement, with clear sky over most parts of the kingdom, but a renewal of unsettled weather was anticipated in the western and northern districts. The rainfall from January 1 is still below the average in most districts, the deficiency amounting to about four inches in the north-east of England, but in the north of Scotland and Ireland the fall is considerably above the average.

THE assistant director of the Meteorological Service of Canada (Mr. B. C. Webber) has prepared a very useful paper entitled "The Gales from the Great Lakes to the Maritime Provinces." The tables show the number of areas of low barometric pressure, and gales, with information regarding them, for each month of thirty-one years (1874–1904). The results are published primarily for the use of the forecast officials in the Dominion, but they are valuable for reference by other persons. On the average, November is the stormiest month on the Great Lakes, and January in the Maritime Provinces; December and February also give a high percentage of storms. The diminution in the number of gales in March and September is opposed to the old idea of the stormy character of the periods of the equinoxes. The author states that the figures afford ample ground for suspicion that towards the maximum of sun-spots there is a maximum of low pressure areas, and that at the sun-spot minimum there is a paucity of such areas. The work has, of course, been prepared under the direction of Mr. R. F. Stupart, the director of the service.

WE have received the *Jahrbücher* of the Austrian Central Office for Meteorology and Terrestrial Magnetism for the year 1903; the work consists of two large quarto volumes, containing (1) carefully prepared results of 400 stations, and (2) special discussions, including an important contribution by M. Margueles on the energy of storms, being an elaborate mathematical analysis of that branch of the physics of the atmosphere; a discussion of much interest for weather prediction, by Dr. F. M. Exner, in connection with the behaviour of the weather during conditions of high atmospheric pressure to the north of the Alps, illustrated by a number of weather charts; also comprehensive researches relating to the formation and propagation of thunder and hail storms, by K. Prohaska. We have before directed attention to the value of the observations made at the high-level stations in the Austrian system; thirty-two of them have an altitude of 1000 to 1500 metres, fifteen others from 1500 to 2500 metres, and the Sonnblick 3106 metres. Meteorologists are much indebted to Dr. Pernter, the able director of the service, for the publication *in extenso* of the hourly results at some of these mountain stations.

MR. WM. BUTLER, of 20 Crosby Road, Southport, whose "swingcam" camera stand was referred to in NATURE of May 25 (p. 89), has sent us a series of twelve small prints of photographs of the recent partial eclipse taken by his son, who is only fifteen years of age, with the use of the apparatus. The pictures are clear, and show several phases of the partial eclipse very distinctly.

A LIST of scientific papers published by the National Physical Laboratory, or communicated by members of the staff to scientific societies or institutions, or to the technical journals, has just been issued. During 1900 and 1904, thirty-three papers on work connected with the laboratory were prepared and published by members of the staff, and in addition eleven papers were published by members of the staff independently.

MESSRS. MACMILLAN AND CO., LTD., will publish shortly "The Chemistry of the Proteids," by Dr. Gustav Mann, of the physiological laboratory at Oxford. This book is based upon the second edition of Dr. Cohnheim's "Chemie der Eiweisskörper," and has been prepared with the author's sanction. Dr. Cohnheim's work, which in its second edition has been entirely re-modelled, is of special interest to professional chemists, both organic and inorganic, but particularly to biologists, including zoologists, physiologists, and pathologists; while among the special features of Dr. Mann's book are, that for the first time the chemical derivatives of albumins and proteids are so arranged as to give a clear idea of the evolution from simple into more complex compounds, and for the first time also a very full account of the synthetic work of Curtius and Fischer is given.

OUR ASTRONOMICAL COLUMN.

NOVA AQUILÆ NO. 2.—Very little further news of Nova Aquilæ is yet to hand, but Circular No. 79 of the Kiel Centralstelle informs us that several visual observations of the star's magnitude and position have been made.

Prof. Max Wolf reports that, according to observations made at the Königstuhl Observatory on September 4, at 9h. 30·0m. (Königstuhl M.T.), the magnitude was 9·3. The position was determined as R.A. = 18h. 54m. 24s., dec. = -4° 39′ (1855).

A telephone message to Kiel from Dr. P. Guthnick on September 6 gave the following positions:—

1855.	R.A. = 18h. 54m. 25s.,	decl. =	-4° 38′·8
1905.	,, 18h. 57m. 4s.,	,,	-4° 34′·8

and stated that the magnitude on September 5 was about 10·2, whilst the star was of a yellowish colour. A star of magnitude 10·5 precedes the Nova by 10s., and is 0′·7 north of it. As the present Nova is the second known to have appeared in the constellation Aquila, it will be designated, according to precedent, Nova Aquilæ No. 2. The first Nova Aquilæ was discovered in July, 1900, on one of the Draper memorial chart plates which had been taken on July 3, 1899, and exhibited the characteristic "Nova" bright-line spectrum. The object itself was recorded for the first time, as a seventh magnitude star, on a plate taken on April 21, 1899.

VARIATION OF A NEWLY DISCOVERED ASTEROID.—According to a telegram from the Kiel Centralstelle, Dr. Palisa has found that the minor planet 1905 QY, which was discovered by Prof. Max Wolf on August 23, is subject to a remarkable fluctuation of magnitude. When discovered,

this asteroid had a magnitude of 11·3, and on August 31 Dr. Palisa recorded it as being of the eleventh magnitude; at 11h. 44m. (Vienna M.T.) on September 5, however, it had sunk to the twelfth.

The position of this body at 11h. 39·9m. (Königstuhl M.T.) on August 23 was R.A.=22h. 37·9m., dec.=$-7° 55'$, and on September 5d. 11h. 4·4m. (Vienna M.T.) R.A.=22h. 27m. 47·3s., dec.=$-9° 5' 45''$.

INTERPRETATION OF SPECTROHELIOGRAPH PICTURES.—In No. 4044 of the *Astronomische Nachrichten*, M. N. Donitch discusses the results obtained by Messrs. Hale and Ellerman, regarding the different chromospheric layers shown on their spectroheliograph negatives, in a new light. He points out that in spectrograms of the chromosphere taken during total eclipses of the sun, the lower layers of the eruptions, *i.e.* those nearer to the moon's limb, appear to be the most extensive, but in Prof. Hale's photographs (plate v., No. 1, vol. xix., of the *Astrophysical Journal*) the opposite appears to be the case, the higher, less dense layers being more extensive than those near to the photosphere.

This discordance between the two results is, in the opinion of M. Donitch, only apparent, and may be explained by the suggestions he advances. He assumes that the inequalities on the surface of the photosphere are so small as to be incomparable with those in the layers of calcium vapour which overlay it. Where this vapour is thin it will only produce the ordinary narrow reversal, producing on the negative a calcium area which is at a low pressure, and, therefore, according to Messrs. Hale and Ellerman, is situated in the upper regions of the chromosphere. This same reversal is also shown by the vapours, which are, in reality, at a greater elevation, so that, using the monochromatic reversal, one obtains on the photograph the forms of the calcium clouds of which the temperature and pressure are relatively low, whatever may be their elevation above the photosphere. For this reason, as M. Donitch believes, the first photograph, which shows more extensive areas of calcium vapour, and according to the Yerkes observers represents simply the upper layers of the disturbed areas, really also represents the thinner extensive layers of vapour which are shown on eclipse spectrograms as the broad bases of the eruptions.

A second photograph taken with the secondary slit set on the *broadened* H reversal (λ=396·2 $\mu\mu$) only registers those layers of calcium vapour which, being part of a thick layer, are subjected to a sufficient difference of temperature and pressure to produce the broadening; and these may, in many cases, be at a greater elevation than the thin layers shown as part of the "calcium" area on the first photograph.

Similarly in regard to the two photographs shown on plate viii. of Messrs. Hale and Ellerman's paper, M. Donitch believes that it is the second, taken with the secondary slit set at λ 3968·6, that reveals the general distribution of the vapours in projection, whereas the first only reproduces the higher agglomerations of the vapour which dominates the lower layer.

THE OBSERVATORY OF PARIS.—M. Lœwy's report for the year 1904 is far too lengthy to be reviewed as a whole in these columns, but one or two of the more important details may be mentioned. In his introduction, the director mentions the progress made during the year in the Eros campaign, and also indicates how the photographs of the moon, taken for the large atlas he is preparing, afford evidence that the moon, and, inferentially, the planets, solidified from the surface towards the centre.

M. Bigourdan has temporarily arrested his observations of nebulæ with the equatorial of the east tower in order that the dome and instrument may be prepared for the determination of the absolute constant of aberration by M. Lœwy's new method.

A study of the garden meridian circle showed that a difference of 0''·45 existed between the readings of the two circles. Various possible causes for this discrepancy were examined, and finally it was discovered that the method of illuminating the microscope wires was at fault. The microscopes have been replaced by others, and the difference thereby eliminated.

The astrophysical department is awaiting the arrival of apparatus before making celestial observations, but in the meantime M. Hamy has carried out several laboratory researches, the chief of which related to the constancy of wave-lengths in the solar spectrum. He found that when the temperature of cadmium vapour in a vacuum tube was raised about 15° C., in the neighbourhood of 300° C., the line at λ 508 diminished several units of the order of $1\ \mu \times 10^{-6}$, and he suggests that the variation of temperature in the solar atmosphere may produce similar results.

During 1904, 80 catalogue and 31 *carte* plates were obtained in connection with the *carte du ciel* operations, whilst 67 plates containing 16,656 star-images were measured.

AN ELECTRIC MICROMETER.[1]

THERE is no finality in experimental measurement. In physics it is a common experience for a present-day worker, with better appliances and a wider horizon than his forerunners, to surpass all previous experimental work in accuracy. As knowledge increases it becomes more minutely exact, and nowadays the physicist has often to measure lengths much less than anything visible in any microscope.

There are various means of measuring small distances. We will take them in order, commencing with the least sensitive:—(1) The unaided eye cannot perceive much less than 1/10 millimetre. (2) With the aid of the microscope the eye can see as little as 1/5000 millimetre. (3) The measuring machine used for engineering gauges will detect differences of 1/8000 millimetre. (4) By using interference bands of light we can perceive movements of 1/100,000 millimetre. (5) In the optical lever a beam of light falls on a pivoted mirror; if a body push the mirror at a point very near the axis of the pivot the beam of light is deflected by a large angle. By this means a movement of the body by 1/400,000 millimetre may be detected. (6) The most modern and sensitive method, the electric micrometer, is due to Dr. P. E. Shaw, who produced it in 1900, and has improved it until he can now measure less than 1/2,000,000 millimetre. The nucleus of the apparatus is shown in the figure. A fine screw M has a graduated head N. The screw in rising pushes up the long arm of a lever pivoted at B. The short arm of the lever falls, and in so doing lets down the long arm of a second lever. This process is carried on through six levers, which all rest under their own weight on the blocks shown. The last lever carries a measuring point P, just above which is a measuring surface Q. If the joint leverage of the lever system be 2000/1, an upward movement of the screw point M by 1/1000 millimetre produces an upward movement of P by 1/2,000,000 millimetre.

As a simple example, suppose we wish to find the thermal coefficient of expansion of the rod R, we proceed thus:—Bring P and Q into contact. The screw M is worked up, while a telephone (Tel.), in the electric circuit shown, is on the observer's head. When P touches Q a circuit is completed, and the telephone sounds. Read the graduated disc N. Now lower the temperature of R by any desired amount, taking care that little or no heat reaches the pillars F' or any part but R. R contracts, and by working screw M up the observer causes P to touch Q again; the telephone sounds, and N is again read. The expansibility can thus be found, when we know the movement of P and the change in temperature.

The screw, the levers, and the frame F' are all carried by a massive girder I. The whole is surrounded by a box thickly wrapped in felt to minimise temperature changes, and is suspended by long rubber cords from the ceiling, to insulate the measuring apparatus from vibration.

The screw M is not touched by hand, but is worked by a pulley cord of rubber which passes from a hand pulley round pulley O. This is done to avoid the comparatively rough touch and tremor of the hand. There are many precautions as to shape, size, cleanliness, and other matters which must be observed.

[1] Based upon a paper by Dr. P. E. Shaw read before the Royal Society.

The smallest measurements ever yet made, viz. 1/2,000,000 millimetre, were in connection with the movements of a telephone diaphragm. The problem was to find what movement of the diaphragm produces a sound which is only just audible.

This is done as follows:—Place a telephone to the ear and pass through it a steady current. On stopping the current a sharp sound is heard in the telephone. Alter the strength of the current until when it is stopped the sound can only just be heard. Observe on a galvanometer the strength of that current (c). Next put the telephone in the electric micrometer in place of the rod R, pass the current (c), and measure the movement of the diaphragm in the usual way. This movement then produces a sound in the telephone which is just audible.

Another use of the instrument is to measure the sparking distance between two surfaces, the potential difference of which is known. The surfaces used are P, Q in the figure. Suppose the potential difference between these surfaces is very small, say 1/1000 volt. Find the contact position as above, and draw P away from Q. Now make the potential difference between P and Q equal to 1 volt. On making P approach Q the contact position has changed by an amount D. Thus the sparking distance for 1 volt is D (supposing the spark distance for 1/1000 volt is negligible). This is found to be about 1/100,000 mm.

In problems on the constitution and molecular properties of matter there are obvious possibilities before this apparatus, for by it we can bring two surfaces of any hard metal to molecular distance (or less) from one another, and keep them there while any desired physical change is produced in the surfaces or in the medium surrounding them.

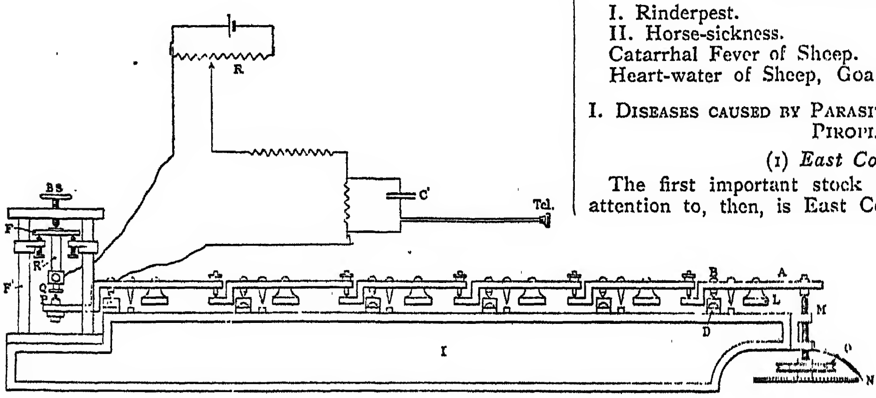

FIG. 1.—The Electric Micrometer.

THE BRITISH ASSOCIATION.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY COLONEL D. BRUCE, M.B., F.R.S., C.B., PRESIDENT OF THE SECTION.

The Advance in our Knowledge of the Causation and Methods of Prevention of Stock Diseases in South Africa during the last ten years.

TEN years ago, when I first came to South Africa, I was led to take an interest in the various great stock diseases which do so much damage and so retard the progress of South Africa as a stock-raising country. I thought, therefore, that a good subject for my address, in the centre of the foremost stock-raising Colony of South Africa, would be a review of the work done in advancing our knowledge, during the last ten years, of the causation and methods of prevention of stock diseases in South Africa. South Africa is particularly rich in animal diseases, every species of domestic animal seemingly having one or more specially adapted for its destruction. Now it is evident that, in an address of this kind, it will be impossible to take up every stock disease, but I think you will agree with me that those shown on this table are among the most important:—

East Coast Fever; ordinary Redwater or Texas Fever; Biliary Fever of Horses; Malignant Jaundice of Dogs; Nagana or Tsetse-fly Disease; Trypanosomiasis of Cattle; Rinderpest; Horse-sickness; Catarrhal Fever in Sheep; Heart-water of Sheep, Goats, and Cattle.

Now we may group these diseases in various ways; for example, as below, where they are divided into two main divisions: *A* division, in which the parasite is known; and *B* division, in which the parasite is unknown.

A. Parasite known.

I. Diseases caused by parasites belonging to the genus Piroplasma:—

(1) East Coast Fever (Koch), *P. parvum*.
(2) Redwater or Texas Fever, *P. bigeminum* (Theiler).
(3) Biliary Fever of Horses, Mules, and Donkeys, *P. equi*.
(4) Malignant Jaundice of Dogs, *P. canis*.

II. Diseases caused by parasites belonging to the genus Trypanosoma:—

(1) Nagana or Tsetse-fly Disease, *T. brucei* (Bradford and Plimmer).
(2) Trypanosomiasis of Cattle, *T. theileri* (Bruce).

B. Parasite unknown.

I. Rinderpest.
II. Horse-sickness.
Catarrhal Fever of Sheep.
Heart-water of Sheep, Goats and Cattle.

I. DISEASES CAUSED BY PARASITES BELONGING TO THE GENUS PIROPLASMA.

(1) East Coast Fever.

The first important stock disease I would direct your attention to, then, is East Coast Fever. This name was given to it by Prof. Robert Koch, of Berlin. In the Transvaal the disease is usually called Rhodesian Redwater. This term is not a good one, since the disease is not restricted to Rhodesia, nor did it arise there, nor is this a disease similar to the ordinary Redwater. Ten years ago, East Coast Fever was unknown in the Transvaal. The first known outbreak occurred only some three and a half years ago, when it broke out at Koomati and Neilspruit, in the Barberton district, and in the east of the Colony. The disease had broken out some time previously in Rhodesia, and the outbreaks in both Colonies were due to infection from Portuguese territory. Although this disease has only been introduced to the country during the last few years, it has already produced an enormous amount of damage among stock, and is probably the most dangerous disease that the people of the Transvaal have to cope with at the present time, and for some years to come.

In the Annual Report of the Transvaal Department of Agriculture there is a most excellent report by Mr. Stockman, the then Principal Veterinary Surgeon, on the work of the veterinary division for the year 1903–1904. A large part of this report is given up to East Coast Fever, and I must here express my indebtedness to Mr. Stockman for much of the following account of this disease. In the same Annual Report there is also an account by Dr. Theiler, the Veterinary Bacteriologist, of the experimental work. Messrs. Stockman and Theiler evidently worked together, and I must congratulate them on the immense amount of good, useful work done by them, and I would also congratulate the Government on having had the services of two such accomplished and energetic gentlemen during the late troublesome times. Unfortunately for the Transvaal, Mr. Stockman has accepted the post of Veterinary Adviser to the Board of Agriculture in England,

but I have no doubt his successor, Mr. Gray, from Rhodesia, will continue the good work begun by him.

East Coast Fever was first studied by Prof. Koch at Dar-el-Salaam, in German East Africa, and he at first mistook it for ordinary Redwater. It seems to occur as an endemic disease along a great part of the East Coast of Africa, but appears to be restricted to a narrow belt along this coast-line. The cattle inhabiting this region have become immune to the disease, and are, therefore, not affected by it. Cattle passing through the Coast district to the interior, or brought to the Coast district from the interior, are apt to take the disease and die. It was by the importation of cattle, therefore, which had passed through the dangerous Coast district that the disease was introduced into Rhodesia and into the Transvaal. On this map which I throw on the screen I have marked out the probable endemic area of this disease, and in the next slide the present distribution of the disease in the Transvaal is also marked out.

Nature of the Disease.—This disease only attacks cattle, but in them is an exceedingly fatal malady: in every hundred cattle attacked only about five recover from the disease. The duration of the disease after the first symptoms have occurred is about ten days.

The cause of the disease is a minute blood parasite called the *Piroplasma parvum* (Theiler). This parasite lives in the interior of the red blood corpuscles.

I now throw on the screen a representation of the blood from a case of Rhodesian Redwater, magnified about a thousand times, showing these small piroplasmata in the interior of the red blood corpuscles. As in the case of so many of these blood diseases, the parasite causing it is carried from the sick to the healthy by means of a blood-sucking parasite. In this particular disease the tick which most commonly transfers the poison or living parasite from one animal to another is known as the "brown tick," *Rhipicephalus appendiculatus*. Koch supposed that the common "blue tick" was the agent. The credit belongs to Dr. Lounsbury and Dr. Theiler of having shown that it is chiefly the "brown tick" which acts as carrier; but Theiler has proved that *R. simus* is also able to transmit the disease. Without the intervention of a tick, so far as we know at present, it is quite impossible that the parasite of this disease can be transferred from one animal to another. For example, if we take a quantity of blood containing enormous numbers of these piroplasmata, and inject it into the blood circulation of a healthy animal, the latter does not take the disease. In the same way, if cattle affected by East Coast Fever are placed among healthy cattle in a part of the country where none of these "brown ticks" are found, the disease does not spread. It is evident, therefore, that some metamorphosis of the parasite must take place in the interior of the tick, and this new form of the parasite is introduced by the tick into a healthy animal, and so produces the disease. In this particular disease the virus or infective agent is not transmitted through the egg of the tick, as is the case in some of these parasitic diseases, but only in the intermediate stages of the tick's development; that is to say, the larva which emerges from the egg of the tick is incapable of giving the disease. What happens is this. The larva creeps on to an infected animal and sucks some of its blood. It then drops off, lies among the roots of the grass, and passes through its first moult. The nympha, which is the name given to the creature after its first moult, is capable of transferring the disease to a healthy animal: that is to say, if it crawls on to a healthy animal and sucks blood from it, it at the same time infects this healthy animal with the germ of E.C.F. In the same way, if a nympha sucks infected blood from a sick animal, it is able, after it has moulted into the adult stage or imago, again to give rise to the disease if placed, or if it crawls, upon a healthy animal.

The Life-history of the Brown Tick.—I throw on the screen a slide representing the four stages of the life-history of the brown tick: The egg, the larva, the nympha, and the adult or imago. The eggs are laid on the surface of the ground by the adult females, which deposit several thousands at a time; and these hatch out naturally, if the weather is warm and damp, in twenty-eight days. But this period of incubation of the eggs may vary very greatly owing to differences in temperature. Immediately after the larva is born it crawls to the summit of a blade of grass or grass stem, and there awaits the passage of some animal. If an ox passes by and grazes on the grass, the tick at once crawls on to the animal, and, having secured a favourable position, starts to suck the ox's blood. It remains on the ox for some three or more days, when, having filled itself with blood, it drops off and lies among the grass. The first moult, under favourable conditions, takes twenty-one days, when the nympha emerges. In the same way the nympha crawls on to an animal and fills itself with blood. As a nympha it also remains on the animal for about three or four days. It again drops off into the grass, and at the end of eighteen days emerges from its second moult as the perfect adult male or female. The males and females again crawl on to an ox, where they mate. After this the female tick ingests a large quantity of blood, which is meant for the nourishment of the eggs, and again drops off, sometimes as early as the fourth day, into the surrounding grass. After about six days she lays her eggs in the ground, and the cycle begins again.

These ticks are very hardy, and in the intermediate stages can resist starvation for long periods, so that a larva or nympha or adult tick may remain perched at the end of a blade of grass for some months without finding an opportunity of transferring itself to a suitable animal. On this account it comes about that even if all infected cattle are removed from a field the ticks in that field will remain capable of transferring the infection to any healthy cattle which may be allowed into this field for a period of about a year. At the end of a year or fifteen months, however, the infective ticks are all dead, and clean cattle may be allowed into the field without any risk. If one takes these facts into consideration it will be seen that a single ox may spread this disease for a distance of some 200 miles, if trekking through the country at the average rate of ten miles a day. For example, an ox is infected by a tick; for fourteen days the animal remains apparently perfectly well; it has no signs of disease, nor has it any fever. It is capable of doing its ten miles' trek a day. At the end of fourteen days the temperature begins to rise, and the animal begins to sicken with the disease, but for the next six days the ox is, as a rule, able to do its ordinary day's march. During most of this time the brown ticks have been crawling on to this ox, becoming infected, and dropping off every three or four days. It can readily, therefore, be seen how much mischief a single infected animal can do to a country between the time of its being infected by the tick and its death some twenty-four days later. As a matter of experience, however, the disease has never been found to make a jump in this way of more than fifty or sixty miles, as, of course, it is very rare that a transport carrier will take his oxen more than that distance during the twenty days.

At the present time it may be said that there are about 500 infected farms in the Transvaal. During last year some 15,000 cattle have died of the disease, and in the affected districts it may be said that there are still some 30,000 cattle alive. When one considers the value of the cattle dead of this disease, which may be said to be about 200,000*l.*, it is evident that money spent on the scientific investigation of the causes and prevention of stock diseases is money well spent. I am informed that all the South African Governments are cutting down their estimates this year, and are inclined to reduce their veterinary staffs and the amounts devoted to research regarding animal diseases. Ladies and gentlemen, if this is so, I have no hesitation in saying that this is the maddest sort of economy and the shortest-sighted of policies.

Methods of combating the Disease.—During the last three years an immense amount of work has been done in the elucidation of this disease—how the animals are infected, how the poison is spread from the sick to the healthy, and so on. In 1903 Prof. Koch was asked by the South African Colonies to study this disease, in order to try to find some method of artificial inoculation or some other means of prevention. He did his work in Rhodesia, and especially directed his energies towards discovering some method of preventive inoculation. At first it was thought that he would be successful in this quest,

as in his second report he announced that he had succeeded in producing a modified form of the disease by direct inoculation with the blood of sick and recovered animals. As you are all aware, the only method of conferring a useful immunity upon an animal is to make it pass through an attack of the disease itself, so modified as not to give rise to above a few deaths in every hundred inoculated. This is the method that has been employed in such diseases as Rinderpest, Anthrax, Pleuro-pneumonia, and many other diseases. The great difficulty in this disease in finding a method of preventive inoculation is the fact that the blood of an affected animal does not give rise to the disease in a healthy one when directly transferred under the skin of the latter. It is only after its passage through the body of the tick that the parasite is able to give rise to the disease in a healthy animal. It is evidently, on the face of it, difficult to so modify the parasite during its sojourn in the tick's body as to reduce its virulence to a sufficient degree.

Prof. Koch in his third and fourth reports recommended that cattle should be immunised by weekly or fortnightly inoculations of blood from recovered animals, extending over a period of five months. Even though this method of Koch had given the desired result, viz. that it rendered the inoculated cattle immune to the disease, it is evident that the method itself can hardly be made a practicable one on a large scale in the field. The expense and trouble of inoculating cattle on twenty different occasions would be very great. It is apparent now that Prof. Koch fell into error through mixing up East Coast Fever with ordinary Redwater. His plan of preventive inoculation was, however, tried on a large scale in Rhodesia by Mr. Gray, now the P.V.S., Transvaal, and found to be useless. At present, therefore, we must look to some other means of preventing the disease and driving it out of the country than preventive inoculation.

Dipping.—Much can be done to prevent the spread of this disease by ordinary methods. For example: in the case of Texas Fever in Queensland dipping cattle in solutions of arsenic or paraffin, in order to destroy the ticks, has met with very fair success; but in the case of this disease we cannot expect to get as good results as in the case of Redwater. The species of tick which conveys Texas Fever remains on the same animal through all its moults, instead of falling to the ground between each different one. If it is not possible to spray or dip cattle oftener than once in ten or fifteen days, it is evident that ticks may crawl upon such animals, become infected, and drop off every three or four days, and so escape destruction by the dipping solution. At the same time every infected tick that is killed by spraying or dipping operations is a source of infection destroyed.

Fencing of Farms.—Again, the fencing of farms must also be useful in the same direction. As the ticks do not travel to any extent when they fall among the grass, it is evident that the cattle on a clean farm which is properly fenced will not become infected by this disease, although all the country round about should be infected. This fencing of farms and subdividing the farm itself into several portions is a most important factor in the prevention of contagious diseases amongst stock. It is, of course, impossible that this can be done at once, as the expense would be prohibitive.

Moving Cattle from Infected Pasture to Clean Pasture.—From a study of this disease and a study of the life-history of the tick it is evident that by a combination of dipping or spraying the cattle so as to destroy almost all the ticks, slaughtering the sick, and moving the apparently healthy on to clean veld—and repeating this, if necessary, a second or third time—it is obvious that by these means, if circumstances are favourable, an outbreak of this disease may be nipped in the bud without much loss to the stock.

Stamping out the Disease.—In May, 1904, an inter-Colonial Conference held at Cape Town resolved that the only effective method of eradicating East Coast Fever is to kill off all the cattle in the infected areas, and to leave such areas free of cattle for some eighteen months. By this means all the centres of infection would be destroyed, and at the end of eighteen months, as all the infected ticks would be dead, it is evident that the disease would be completely stamped out. There is no doubt that this drastic method would be the quickest and most complete one of getting rid of this extremely harassing disease. If compensation were given, it could be done at a cost of, say, a quarter of a million. The Government decided, however, that on account of the difficulty of carrying out such a drastic scheme another policy had to be considered. This policy provides for the fencing-in of infected farms, places, lands, or roads, on generous terms; the compulsory slaughter of stock with compensation in the case of isolated outbreaks; the removal of all oxen from infected or suspected farms; and, lastly, the stabling of milch cows in infected areas. It is quite evident that under this less drastic policy the final stamping-out of the disease will be a much slower process than if the more drastic scheme of compulsory slaughter of all cattle on infected areas had been carried out. The benefits, however, from the modified scheme are undoubted; and if carried out thoroughly and intelligently for a period of several years will probably result in the stamping-out of the disease.

Allow me to sum up in regard to the advance in our knowledge of this important stock disease during the last ten years. Ten years ago nothing was known. Now the causation of the disease has been made out very fully; the parasite that causes it is known; the ticks which carry the infection are known. Although no method of conferring immunity on healthy cattle has been found out, or any medicinal treatment discovered which will cure the sick animal, yet our knowledge of the life-history of the parasite and the ticks enables regulations to be framed which, if patiently carried out, must be crowned with success.

(2) *Redwater or Texas Fever.*

I may dismiss this disease in a few words. It is a most interesting disease and of great importance to stock farmers. It only affects cattle.

Geographical Distribution.—It is a disease found in almost every part of the world. It was first studied in North America; hence the name Texas Fever. To Kilborne and Smith is due the honour of elucidating the causation of this disease, and their work forms one of the most interesting chapters in the history of pathological science. They discovered that it was caused by the presence in the red blood corpuscles of a protozoal parasite closely related to the parasite found in E.C.F.—the *Piroplasma parvum*. This organism is called *Piroplasma bigeminum*. They further discovered that this parasite was conveyed from sick to healthy cattle by means of a tick. They also showed that the cattle born and bred in certain southern districts are immune to the disease, whereas cattle in the northern districts are susceptible. Hence, if southern cattle were driven into the northern district, they gave rise to a fatal disease among the northern cattle; and, *vice versâ*, if the susceptible northern cattle were driven into the southern district among the apparently healthy cattle of that district, they took Texas Fever and died.

Texas Fever was introduced about 1870, and is now endemic throughout most of South Africa. For many years the native cattle have been immune to the disease; that is to say, on account of being born and bred in a Texas Fever locality they had inherited a degree of resistance to the disease which enabled them to pass through an attack when they were young, and so they became immune. But there is one peculiarity about Texas Fever which does not occur in Rhodesian Tick Fever, and that is that the blood of an animal which has recovered from Texas Fever remains infective—the germs remain latent—and so the native cattle of South Africa, although apparently healthy, are capable of infecting imported susceptible cattle with this very fatal malady. This is what makes it so difficult to import prize stock into this country.

When the Boers visited Mooi River, at the beginning of the war, they found a prize short-horn carefully stabled in Mr. P. D. Simmon's farm. They killed most of his stock for food, but left this short-horn bull alive. When they left the farm they turned this bull into the nearest field, in order, of course, that it might procure food. They had much better have eaten it. It promptly took Texas Fever and died.

This disease, then, has become of secondary importance

to South Africa in these days. The native cattle have become naturally immune, and the disease is only fatal to susceptible imported cattle. This, of course, discourages the importation of prize stock; but with the knowledge we possess it ought to be possible, by good stabling and prevention of contact with tick-infected cattle, to keep the prize stock alive for a reasonable time. The question of the feasibility of immunising the prize stock while calves in England might be considered.

In regard to methods of conferring immunity on susceptible cattle many have been tried, but none are absolutely free from risk.

We may sum up in regard to Redwater or Texas Fever by saying that our knowledge of its causation and methods of prevention is much the same as it was ten years ago. The work done by Smith and Kilborne on this disease was of such a brilliant nature, and was done so thoroughly, that little has been left for later workers to do.

(3) *Biliary Fever of Horses, Mules, and Donkeys.*

This is a disease of horses, mules and donkeys very similar to Redwater in cattle, and is caused by a closely allied parasite, the *Piroplasma equi*, discovered for the first time in South Africa by Bordet, Danysz, and Theiler, and named by Laveran of Paris.

It is similar to Redwater, in that animals which have recovered from the disease remain a source of infection during the remainder of their lives to susceptible animals. The native South African horse is, like the cattle, immune to the disease. It is also conveyed by a tick, which has been shown by Theiler to be the "red tick" (*Rhipicephalus evertsi*), the infection being taken in the nymphal and transferred in the adult stage. Theiler has also made the very important observation that if a horse is injected with blood from a donkey which has recovered from the disease, as a rule a mild form of the disease is produced, so that this opens up a method of immunising susceptible horses which may probably prove of practical value. Theiler has also made another curious discovery. This disease of horses was found to greatly complicate certain immunising experiments he was making against Horse-sickness. He found he was introducing the *Piroplasma equi* at the same time he injected Horse-sickness virus. But he found out that as the virus of Horse-sickness keeps its virulence for years, whilst the *Piroplasma equi* dies out in a short time, this danger could be avoided by keeping the Horse-sickness serum and virus for some time before using it.

(4) *Malignant Jaundice of Dogs.*

This disease is most important to sportsmen or to importers of valuable dogs, as most of these are attacked sooner or later by this disease, and most of them succumb. It is also caused by a species of Piroplasma (*Piroplasma canis*), and is spread by the dog tick (*Haemophysalis leachii*).

Like Redwater and Biliary Fever, the blood of dogs which have recovered remains infective.

The story of the tick infection is a curious one, and the credit of its discovery is due to Lounsbury. It is only in the adult stage that the tick is capable of producing the disease. It is therefore evident that the Piroplasma must remain latent in the egg, the larval and nymphal stages, and only attain activity in the adult stage.

According to Theiler there exists a peculiar phenomenon which may be made use of to confer immunity. The blood of a dog which has recovered from this disease and has been hyper-immunised is, as mentioned above, capable of giving rise to the disease in a susceptible dog. Now, if serum be obtained from this blood and a quantity added to a small amount of the blood, this infected blood loses its infectivity and no disease results.

II. DISEASES CAUSED BY PARASITES BELONGING TO THE GENUS TRYPANOSOMA.

(1) *Nagana or Tsetse-fly Disease.*

We now come to the second group of diseases. These are also caused by blood parasites belonging to the same class of living things as the Piroplasma, but which are free organisms, swimming in the fluid part of the blood, and not contained in the red blood corpuscles, as are the others.

The first of this group I would direct your attention to is that disease called *Nagana* or the *Tsetse-fly Disease*.

This fly renders thousands of square miles of Africa uninhabitable. No horses, cattle, or dogs can venture, even for a day, into the so-called "Fly Country." Now what was our knowledge of this disease ten years ago? At that time it was thought that the tsetse-fly killed animals by injecting a poison into them, in the same way as a snake kills its prey. Nothing was known as to the nature of this poison in 1894. In 1895, on account of serious losses among the native cattle in Zululand from this plague, the then Governor of Natal and Zululand, Sir Walter Hely-Hutchinson, started the investigation of this disease. The result of this investigation was the discovery that Tsetse-fly Disease was not caused by a simple poison elaborated by the fly, as formerly believed, but that the cause of the disease was a minute blood parasite which gained entrance to the blood of the animals. This parasite is known by the name Trypanosoma, which signifies a screw-like body.

Ten years ago two species only had attracted much attention—one living in the blood of healthy rats, discovered by Surgeon-Major Lewis in India; and the other, a trypanosome, found in the blood of horses and mules suffering from a disease known in India as "Surra." As the result of this investigation in Zululand, which lasted two years, it was proved that this trypanosome was undoubtedly the cause of the death of the horses and cattle struck by the fly, and that the tsetse-fly merely acted as a carrier of this blood parasite.

Here is a representation of the trypanosome of Nagana on the screen. These trypanosomes consist of a single cell; are sinuous, worm-like creatures, provided with a macronucleus and a micronucleus, a long terminal flagellum, and a narrow fin-like membrane continuous with the flagellum and running the whole length of the body. When alive they are extremely rapid in their movements, constantly dashing about, and lashing the red blood corpuscles into motion with their flagellum. They swim equally well with either extremity in front. These organisms multiply in the blood by simple longitudinal division, and often become so numerous as to number several millions in every drop of blood. They are sucked, along with the blood, into the stomach of the fly, live and multiply in the alimentary tract for several days, and, when the fly has its next feed on an animal, take the opportunity of gaining access to the blood of the new host, and so set up the disease.

Let me now throw on the screen a representation of the tsetse-fly (*Glossina morsitans*) which does all the mischief. Experiments were made which showed that the fly could convey the parasite from affected to healthy animals for at least forty-eight hours. It is a curious fact that among all the blood-sucking flies the tsetse-fly alone has this power, and up to the present the cause of this has not been thoroughly cleared up. Lately, however, evidence has been brought forward to show that an enormous multiplication and development of the trypanosomes take place in the fly's intestine, a few trypanosomes multiplying to masses containing numberless parasites within twenty-four hours. Now, if this multiplication only takes place in the intestine of the tsetse-fly, and not in the other kinds of biting flies, this would probably account for the curious connection between the tsetse-fly and the disease. This multiplication of the trypanosomes in the tsetse-fly was discovered by Gray and Tulloch, two young army medical officers, while working in Uganda on "Sleeping Sickness" during the present year.

Not only was it found that the tsetse-flies could convey the disease from sick to healthy animals, but it was also proved that the wild tsetse-flies brought from the "Fly Country" and straightway placed on healthy animals also gave rise to the disease. The question then arose as to where the tsetse-flies living in the "Fly Country" came by the trypanosomes. There were no sick horses or cattle in the "Fly Country." Investigation brought to light the curious fact that most of the wild animals—the buffalo, the koodoo, the wildebeeste—carried the trypanosomes in small numbers in their blood, and it was from them that the fly obtained the parasite. The wild animals act as a reservoir of the disease. The trypanosome seems to live in the blood of the wild animals without doing them any

harm, just as the rat trypanosome lives in the blood of healthy rats; but when introduced into the blood of such domestic animals as the horse, the dog, or ox it gives rise to a rapidly fatal disease. The discovery that the wild animals act as a reservoir of the disease accounted for the curious fact that Tsetse-fly Disease disappears from a tract of country as soon as the wild animals are killed off or driven away.

In 1895 the living trypanosome which causes the Tsetse-fly Disease was sent to England in the blood of living dogs, in order that it might be studied in the English laboratories. These trypanosomes have been kept alive ever since by passage from animal to animal, and have been sent all over Europe and America, so that our knowledge of this kind of blood parasite has rapidly grown.

Koch, in a recent address, says that our knowledge of protozoal diseases is based on three great discoveries—that of the malarial parasite, by Laveran; of the *Piroplasma bigeminum*, the cause of Texas Fever or Redwater in cattle, by Smith; and, lastly, this discovery of a trypanosome in Tsetse-fly Disease.

We may, therefore, I think, congratulate ourselves on the growth of our knowledge of this great stock disease during the last ten years.

Since 1895 many other trypanosome diseases have been discovered in all parts of the world. The latest and most important of these is one which affects human beings, and is known as "Sleeping Sickness." This "Sleeping Sickness," which occurs on the West Coast of Africa, particularly in the basin of the Congo, has within the last few years spread eastward into Uganda, has already swept off some hundreds of thousands of victims, is spreading down the Nile, has spread all round the shores of Lake Victoria, and is still spreading southward round Lakes Albert and Albert Edward. This disease is in all respects similar to the Nagana or Tsetse-fly Disease of South Africa, except that it is caused by another species of trypanosome and carried from the sick to the healthy by means of another species of tsetse-fly—viz. the *Glossina palpalis*.

I now throw on the screen a map of Africa, showing, so far as is known up to the present, the various fly districts, and you will see from this map that it is not at all improbable that this human Tsetse-fly Disease may spread southward through the various fly districts to the Zambesi, and may even penetrate as far as the fly districts of the Transvaal and Zululand.

I am sorry to say that, in spite of innumerable experiments directed towards the discovery of some method of vaccination or inoculation against these trypanosome diseases, nothing definite, up to the present time, has been discovered. At present there does not seem to be any likelihood that a serum can be prepared which will render animals immune to the Tsetse-fly Disease. In the same way it has also been found impossible, up to the present, to so modify the virulence of the trypanosome as to give rise to a modified, non-fatal form of the disease. Again, all attempts at discovering a medicine or drug which will have the power of killing off the parasites within the animal organism, without at the same time killing the animal itself, have not as yet been successful, although some drugs, such as arsenic and certain aniline dyes (Ehrlich), have a very marked effect in prolonging the life of the animal. As this disease is fatal to almost every domestic animal it attacks, it seems very improbable that there is much chance of cultivating an immune race of horses, dogs, or cattle which will be able to withstand the action of the parasite. It is quite evident that if an acquired immunity of this kind could be brought about, such a race of immune animals would now be found; but, as a matter of fact, there are no horses, dogs, or cattle in the "Fly Country." In other protozoal diseases, such as the Piroplasmata, this acquired immunity seems to come about fairly readily.

To sum up, then, the increase in our knowledge of Tsetse-fly Disease during the last ten years, we may say that we have discovered the cause in the shape of the small blood parasite Trypanosoma; we have found that the reservoir of the disease exists in the wild animals, and that we can blot out this disease from any particular tract of country by the simple expedient of destroying or driving away the wild animals. We still have no means of preventive inoculation or successful medicinal treatment in this disease.

(2) *Trypanosomiasis of Cattle.*

This disease seems to be widespread over all South Africa. It cannot be said to be of much practical importance, as the cattle infected do not seem to be seriously affected by it. It is caused by a species of trypanosome remarkable for its large size, which was discovered by Dr. Theiler some years ago, and named *T. theileri.*

Dr. Theiler states that it is conveyed from animal to animal by the common horse-fly, *Hippabosca rufipes.*

This, then, is a short account of the trypanosome diseases which affect South Africa.

Of late years the Tsetse-fly Disease has become of less practical importance to the Transvaal, from which it has practically disappeared. This is due to the disappearance of the game, killed off by Rinderpest; but with the preservation and restoration of the reserves with big game the disease is certain to reappear. Why the fly should disappear with the game is not known.

B. Parasite unknown.

I. *Rinderpest.*

We now turn our attention to the important diseases of the second group. In these the parasites causing them are unknown—that is to say, no parasites can be detected by the microscope or by culture—but it is equally true that they must be present in the blood and fluids of the sick animals in some form or other. In all probability they are ultra-microscopic—too small to be seen with our present instruments. This is borne out by the fact that they are able to pass through the pores of porcelain filters, which keep back the smallest micro-organisms we are able to recognise.

The first of the second group of diseases is Rinderpest, which has overrun and devastated South Africa within the last ten years.

Rinderpest has been known from time immemorial in Europe and Central Asia, and is an exceedingly fatal disease, killing 90 to 100 per cent. of the cattle attacked.

The recent epidemic, according to some, originated in the Nile provinces, and slowly crept southwards, reaching the Transvaal in 1896, after a journey lasting some fifteen years. Great efforts were made to oppose its passage, but nothing seemed to avail. In parts of the country where there were few or no cattle the epidemic spread by means of the wild animals—particularly the buffalo—which have been exterminated in many places.

Ten years ago the symptoms and contagious nature of this disease were well known, but nothing was known as to methods of prevention, and it is to the investigation of this epidemic in South Africa that the discovery of practical methods of immunising cattle, and in this way of stamping out the disease, is due.

As soon as it was apparent that the epidemic was spreading into South Africa, all the Colonies made strenuous efforts to combat it. The Transvaal Government invoked the aid of the Pasteur Institute, and Messrs. Bordet and Danysz were sent out to discover some method of prevention. They worked near Pretoria, and were assisted by Dr. Theiler, then the Principal Veterinary Surgeon. Before they arrived on the scene the Natal Government had dispatched Mr. Watkins-Pitchford, their Principal Veterinary Surgeon, to the Transvaal, where he also at first had Dr. Theiler as his colleague, and where he did some good pioneer work in the serum therapeutics of the disease. In the Cape Colony Dr. Hutcheon, the Principal Veterinary Surgeon, and Dr. Edington, the Government bacteriologist, were no less active. It is, however, to Prof. Robert Koch, of Berlin, that the honour is undoubtedly due of first publishing a practical method of immunising cattle against Rinderpest. He arrived at Kimberley on December 5, 1896, and in the incredibly short space of time of two months was able to report two methods of immunising, viz. by the injection of Rinderpest bile, and, secondly, by the injection of serum from immune animals. I have always thought that the discovery that the injection of bile taken from an animal dead of Rinderpest rendered cattle immune was particularly

brilliant. Up to that time no one had dreamt that bile could possess such a quality. It is true that both Transvaal and Orange Free State Boers are said to have used a mixture of bile and blood from dead animals before Koch's researches, and also that Semmer in 1893 showed that serum might be used for protective purposes; but still to Koch is due the credit of making these processes practical. After he left South Africa his work was continued by Kolle and Turner, who greatly improved the methods; and it is to them, and to the other workers mentioned above, that we owe the fact that Rinderpest has now lost its terrors.

In the last recrudescence of this disease in the Transvaal, in 1904, Mr. Stewart Stockman, the Principal Veterinary Surgeon, and Dr. Theiler, thanks to the experience and knowledge gained during the last ten years, were enabled to stamp out the disease rapidly and completely. It is to them also that we owe our knowledge of the dangers of the intensive method of inoculation, much used in the past and due to Kolle and Turner, and the introduction of the fighting against the plague by the inoculation of the healthy cattle by injections of immune serum alone.

In the Tsetse-fly Disease our advance in knowledge has been in regard to the causation of the disease, and not in its prevention; it is quite otherwise with Rinderpest. The contagion or cause of Rinderpest is absolutely unknown. We know it exists in the blood, nasal, mucous, and other secretions of the sick animal, as all these are infective, but no one has seen it. The smallest quantity of blood will give the disease if injected under the skin of a healthy animal. We also know that the contagium is not very resistant. Blood soon loses its virulence after it leaves the body, and the effect of drying or the addition of chemical preservatives, such as glycerin, act also injuriously to the contagium, whatever it may be. It evidently belongs to the ultra-visible sort of micro-organisms, as it is said to pass through a porcelain filter.

How the contagium passes from the sick to the healthy is assumed to be by contact. No experiments have, so far as I am aware, been made as to whether it is conveyed by insects as well; but, as Prof. John MacFadyean says, as it spreads in all countries and climates and seasons, and the contagium is easily carried on the persons or clothes of human beings, it is improbable that insects have anything to do with it.

It is in the methods of protective inoculation that the great advance has been made in our knowledge of this disease. Ten years ago no means were available to stay the progress of this plague; now it has lost its terrors. As soon as it appears it can be immediately attacked and stamped out. This is done by rendering the surrounding cattle immune to the disease by injecting immune serum. This serum is prepared by taking immune cattle and hyper-immunising them by the injection of large quantities of virulent blood, so as to make their blood serum as anti-toxic as possible. If there are no immune cattle at hand, cattle can be immunised by Koch's bile injection method and then hyper-immunised; but, of course, in practice—for example, here in the Transvaal—large quantities of immune serum are kept ready for emergencies, and a herd of immune cattle kept up for the supply of the serum. This satisfactory state of affairs, so far as this disease is concerned, is, of course, the outcome of an immense amount of thought and experiment, and I have already mentioned the chief scientific men to whom this country owes this great boon.

Different methods of immunising have been tried during these years. Up to 1903 the prevailing custom was to use what was known as the virulent-blood and serum method. That is to say, immune serum and virulent blood were injected at the same time, in order that the animal might pass through a modified attack of the disease. Since 1903, however, in the Transvaal this method has been stopped, and the "serum alone" method introduced. This method is based on the fact that the virus of Rinderpest does not retain its infective property outside the body for more than a day or two; that it dies out in the animal, as a rule, in fourteen days, but in chronic cases only after thirty days, and that therefore the healthy cattle in an affected herd must be protected for this length of time. Now "serum alone" only protects for about ten days, and therefore the cattle must be inoculated three times at intervals of ten days. The doses of serum must also be large—from 50 c.c. to 200 c.c.—so that this method of stamping out Rinderpest, although quite efficacious, entails a good deal of labour. It is necessary, then, to spare no expense in making the Veterinary Department efficient, and any cheese-paring legislation in this direction may be disastrous.

II. *Horse-sickness.*

The next stock plague I would bring before your notice is Horse-sickness. This is a disease which only affects equines—the horse, mule, and rarely the donkey. It is a very fatal disease, carrying off thousands of horses every year. It is one of the most important diseases in South Africa, and, if it could be coped with, would enable the Transvaal to become one of the best horse-breeding countries in the world. At present it is dangerous for anyone in Natal and many parts of the Transvaal to possess a valuable horse, the chances of losing it by Horse-sickness being so great.

In 1895, when I went to the north of Zululand with the Ingwavuma Expedition, we lost all our horses with this disease. We started with a hundred horses, and had to march back on foot, every horse having died.

Ten years ago, when I arrived in South Africa, our knowledge of this disease was confined to the disease itself; nothing was known as to its causation or prevention. Credit is due to Dr. Edington for having accurately described the lesions and shown its ready inoculability, period of incubation, &c. He, however, fell into the mistake of attributing its causation to a species of mould fungus.

Etiology: Geographical Distribution.—Horse-sickness is widely distributed throughout Africa. It is common in Natal, Zululand, the greater part of the Transvaal, Rhodesia, Bechuanaland, and Portuguese East Africa. In Cape Colony it occurs in epidemics, with intervals of ten to twenty years. It is undoubtedly a disease which prevails chiefly *in low-lying localities* and valleys, and is but rarely met with in elevated exposed positions. It, however, is met with now and then in river valleys up to an elevation of some thousands of feet. *Season* has also a remarkable influence on its development, being exceedingly common in summer and disappearing on the appearance of the first frosts of winter.

Ten years ago various theories were held as to the cause of this disease. Some people thought that it was due to eating poisonous herbs; others, to some peculiarity or state of the night atmosphere; others, to eating grass covered with dew; and still others, to the eating of the spiders' webs which may be seen on the grass in the morning. It was known at that time not to be contagious in the ordinary sense of that term; that is to say, a horse could be stabled alongside a case of Horse-sickness without incurring the disease, or a horse might be placed without danger in the same stall in which a horse had recently died of Horse-sickness.

Nature of the Disease.—A horse which has been exposed to infection shows no signs of the disease for about a week. Its temperature then goes up rapidly, and it dies after four or five days' illness. Very often the horse appears perfectly well until within a few hours of death. For example, my horse was the last one to die on the Ingwavuma Expedition. On the day of his death I rode him until noon without noticing anything amiss. He then became rather dull in his movements, and I handed him over to the groom to lead. He died that evening immediately after we got into camp. It is, therefore, a very rapidly fatal disease, and almost every horse which is attacked by it succumbs. I have never seen a case of Horse-sickness which had been brought on by artificial inoculation recover. But there can be no doubt that a small percentage of horses infected naturally do recover, and these recovered horses are, more or less, immune in future to the disease. There is no necessity for me to describe the symptoms of this well-known disease, as everyone who has to do with horses in South Africa is perfectly familiar with it, and everyone has seen dead horses with the characteristic mass of white foam issuing

from their nostrils, due to the effusion of the liquid part of the blood into the lungs and trachea.

Nature of the Virus which causes this Disease.—There can be no doubt that this disease, like the Tsetse-fly Disease, is caused by some form of blood parasite. A small quantity of fluid taken from any part of a horse suffering from Horse-sickness is capable of giving rise to the disease if injected under the skin of a healthy horse. For example: the thousandth part of a drop of blood from a sick horse will, in many cases, give rise to the disease if injected under the skin of a healthy horse. It must be admitted, however, that some horses require a larger dose than others, but it may be said that no horse has yet been found to withstand more than a comparatively small quantity of infective blood thrown under the skin. Now, although every drop of blood must contain many of the organisms of this disease, yet the most careful examination of such blood under the highest powers of the microscope reveals nothing. Again, if we filter Horse-sickness blood through a porcelain filter—a filter which is capable of keeping back all the known visible micro-organisms—the filtrate is found to be virulent. It is evident, then, that we are here dealing with a blood parasite so small in size as to be absolutely invisible to the highest powers of the microscope, and also so minute as to readily pass through the pores of a Chamberland filter. What the nature of this parasite is one cannot tell. It behaves in many curious ways. For example, Horse-sickness blood which is simply dried and pounded into powder is found to be perfectly inert. On the other hand, blood kept in the moist condition remains virulent and capable of giving rise to the disease for years. Or, again, the germ of Horse-sickness is so resistant to external agencies that if, as described by MacFadyean, a part of the liver of a horse dead from Horse-sickness be buried in the ground and subjected to putrefaction, it is found that the liver tissue retains its infectivity for months. Although a very small quantity of blood introduced under the skin of a horse will almost certainly give rise to the disease, it is quite different if the blood is introduced into the stomach. In the latter case a small quantity of blood has no effect, and the horse requires to be drenched with a pint or more before the disease can be given in this way.

The question now arises as to how horses are infected by this disease in Nature. On account of the small quantity of blood which will give rise to the disease if injected under the skin, and the large quantity required before the disease can be conveyed through the stomach, for a long time it has been supposed that it must be conveyed from sick to healthy horses by means of some biting insect. Experiments have been made within the last few years by Watkins-Pitchford and others in order to clear up this aspect of the question. Horses have been placed in fly-proof shelters in exceedingly unhealthy places, and it was found that in no case did any of these protected horses incur the disease; whereas horses allowed to feed in the same place, but without any shelter, soon succumbed to the disease. But, up to the present, so far as I am aware, the particular biting fly, mosquito, or other insect which is the carrier of this disease has not been discovered, and there can be no doubt that one of the most important facts to make out in the etiology of this disease is the discovery of the particular insect which conveys the disease from the sick to the healthy. By this discovery a flood of light may be thrown on the causation of the disease, and some means discovered of combating the disease through the insect, as has been successful in some instances in regard to the case of human malaria.

Prof. MacFadyean also suggests that experiments are needed to show what is the "reservoir" of the virus.

Prevention.—Although we have been unfortunate up to the present in not being able to make out the exact nature of the parasitic cause of this disease, or to discover the exact insect which carries it, a large amount of patient persevering work has been done within the last ten years in regard to its prevention by protective inoculation.

In this important work Bordet, Edington, Koch, Theiler, Watkins-Pitchford, and others have laboured for many years, and, according to recent reports, with some measure of success.

Dr. Edington, for example, who has been working at this problem for several years, reports that Heart-water is identical with Horse-sickness, and that by inoculating mules with Heart-water blood he has been able to salt them against Horse-sickness. He says that experiments testing this vaccine show it to be an ideal one. It gives a high protection to the animals inoculated. Its keeping powers are excellent. No animal has died as the result of this inoculation nor has any dangerous symptom been produced. He states that he is not in a position to supply a vaccine for Horse-sickness in horses, but has every hope of attaining this successful end very shortly.

We must congratulate Dr. Edington on his results, and trust that this method of conferring immunity may prove itself to be successful when put to practical use. For my part, I am somewhat sceptical of Dr. Edington's methods of immunising against Horse-sickness. I am sure he will forgive my expression of scepticism when I recall to his memory the various methods he has already brought forward, just as optimistically, which have all been tried and found wanting.

Dr. Koch has lately recommended a method of immunisation against Horse-sickness. This is the artificial establishment of an active immunity in susceptible animals by gradually increased doses of virulent blood, alternated in the early stages of treatment with the injection of serum prepared from the blood of highly fortified salted horses. Mr. Gray reports that the experiments already conducted on these lines show that the process as laid down by Koch requires important modification before the process of establishing immunity against Horse-sickness can be of any practical use.

Mr. Watkins-Pitchford in Natal is also hopeful of succeeding in producing immunity against Horse-sickness.

Dr. Theiler, too, reports that he has succeeded in producing a serum which can be utilised in connection with virulent blood to confer active immunity. He informs me that his method is a subcutaneous injection of serum and an intra-jugular injection of virus carried out simultaneously. The death rate in mules, from the effect of the inoculation, he states to be about 5 per cent. It is higher in horses, but he expects shortly to attain the same result in them. During the last Horse-sickness season he exposed 200 immunised mules to natural infection in various parts of the country. Of that number only one died with symptoms of Horse-sickness. As Dr. Theiler is himself communicating his method in detail to the Association, I need not enter more fully into it.
